# BOUNDED APPROXIMATION BY POLYNOMIALS ${ }^{1}$ 

BY L. A. RUBEL AND A. L. SHIELDS<br>Communicated by Maurice Heins, April 22, 1963.

We announce a complete solution to the following problem. If $G$ is an arbitrary bounded open set in the complex plane, which com-plex-valued functions in $G$ can be obtained as the bounded pointwise limits in $G$ of a sequence of polynomials?

Theorem. Given an arbitrary bounded open set $G$ in the complex plane, and a complex-valued function $f$ defined on $G$. There exists a sequence $\left\{p_{n}\right\}$ of polynomials that are uniformly bounded on $G$ and that converge pointwise on $G$ to $f$ if and only if $f$ has an extension $F$ that is bounded and holomorphic on $G^{*}$, where $G^{*}$ is the inside of the outer boundary of $G$.

More precisely, $G^{*}$ is the complement of the closure of the unbounded component of the complement of the closure of $G$.

In a certain sense, this result lies somewhere between Runge's theorem and Mergelyan's theorem [3]. The correct formulation of our theorem is in terms of sequences, and not topological closure. Indeed, for a certain bounded open set $G$, there exists a function $f$ and functions $f_{n}$ such that (i) each $f_{n}$ is the bounded limit of a sequence of polynomials, (ii) $f$ is the bounded limit of $f_{n}$, but (iii) $f$ is not the bounded limit of any sequence of polynomials.

With $G$ and $G^{*}$ as above, we write $B_{H}(G)$ for the set of bounded holomorphic functions on $G$, and $B_{H}\left(G^{*}: G\right)$ for the set of functions on $G$ that have a bounded holomorphic extension to $G^{*}$, and $P(G)$ for the set of functions on $G$ that can be boundedly approximated on $G$ by a sequence of polynomials. The theorem now reads:

$$
P(G)=B_{H}\left(G^{*}: G\right)
$$

Even if $G$ is connected and simply connected, it may happen that $G^{*}$ has several components. We define $G^{\#}$ as the union of those components of $G^{*}$ that intersect $G$. Clearly, $B_{H}\left(G^{*}: G\right)=B_{H}\left(G^{*}: G\right)$.

As a corollary to the theorem, we get a characterization of those bounded open sets $G$ on which each bounded holomorphic function can be boundedly approximated by polynomials, namely $P(G)$ $=B_{H}(G)$ if and only if $B_{H}(G)=B_{H}\left(G^{*}: G\right)$; in other words, if and only if the inner boundary of $G$ is a set of removable singularities for all bounded holomorphic functions on $G$. The inner boundary of

[^0]$G$ is that part of the boundary of $G$ that does not intersect the unbounded component of the complement of $G$ closure.

For example, if $G$ is the open unit disc, then $G^{*}=G$, and hence $P(G)=B_{H}(G)$. This is a classical result; in this case, the sequence of arithmetic means of the partial sums of the power series of $f$ converges boundedly to $f$. A proof that $P(G) \supseteq B_{H}(G)$ if $G$ is a Jordan domain is given in [2, pp. 3-5]. If $G$ is the punctured unit disc, then $P(G)$ $=B_{H}(G)$, but if $G$ is the unit disc with a radius removed, then $P(G)$ $\neq B_{H}(G)$. It may happen that $G=G^{\sharp}$, and consequently $P(G)=B_{H}(G)$, even though the closure of $G$ separates the plane. This is the case if $G$ is a spiral ribbon, with infinitely many turns, that winds down onto the unit disc.

The proof of the theorem is long, with complications arising if $G$ has infinitely many components. We give here a crude sketch of a line of proof that works in the special case where $G$ is connected, which is considerably easier than the general case. We must show that $P(G)=B_{H}\left(G^{\sharp}: G\right)$.

First, $P(G) \subseteq B_{H}\left(G^{\#}: G\right)$, since if the sequence $\left\{p_{n}\right\}$ of polynomials converges boundedly to $f$, then the $p_{n}$ are uniformly bounded on the outer boundary of $G$, hence on the boundary of $G^{\#}$ also, and the $p_{n}$ are consequently uniformly bounded in $G^{*}$. Hence, some subsequence converges on $G^{\#}$ to a bounded holomorphic function which must be an extension of $f$.

In the other direction, there exist simply connected regions $G_{n}$, with $G_{n+1} \subseteq G_{n}$, and the closure of $G^{\#}$ contained in each $G_{n}$. The regions $G_{n}$ "squeeze down" onto $G^{\#}$ in the sense that $G^{*}$ is the largest connected open superset of $G$ that is contained in $\cap G_{n}$. We construct the regions $G_{n}$ as the insides of a sequence of equipotential curves of the logarithmic equilibrium potential on $G$. By a theorem of Carathéodory [1, p. 76], if $\phi_{n}$ is the normalized mapping function of $G_{n}$ onto the unit disc, then the $\phi_{n}$ converge to $\phi$ on $G^{\#}$, where $\phi$ is the normalized mapping function of $G^{\#}$. Given $f$ in $B_{H}\left(G^{*}\right)$, the functions $f_{n}=f \circ \phi^{-1} \circ \phi_{n}$ converge boundedly in $G^{\#}$ to $f$. By Runge's theorem, $f_{n}$ can be approximated on $G^{\#}$ by a polynomial $p_{n}$, with a uniform error at most $1 / n$. The polynomials $p_{n}$ converge boundedly to $f$ in $G^{\#}$, and a fortiori in $G$. Thus $B_{H}\left(G^{\sharp}: G\right) \subseteq P(G)$. This completes the sketch of the proof for the special case.

# DOUBLY INVARIANT SUBSPACES OF ANNULUS OPERATORS 

BY DONALD SARASON ${ }^{1}$<br>Communicated by P. R. Halmos, April 29, 1963

1. Introduction. Let $C$ be the unit circle in the complex plane and let $C_{0}$ be the circle $\left\{z:|z|=r_{0}\right\}$, where $r_{0}$ is a positive real number less than unity. The set $C \cup C_{0}$ is the boundary of the annulus $A=\left\{z: r_{0}<|z|<1\right\}$. Let us endow the circles $C$ and $C_{0}$ with Lebesgue measure of total mass unity, and denote by $L^{2}(\partial A)$ the $L^{2}$ space associated with the measure thereby defined on the set $C \cup C_{0}$. This note concerns the invariant subspaces of the position operator on the space $L^{2}(\partial A)$, that is, of the operator $Z$ on $L^{2}(\partial A)$ defined by $(Z x)(z)$ $=z x(z)$.

We may regard $L^{2}(\partial A)$ as the direct sum of the two spaces $L^{2}(C)$ and $L^{2}\left(C_{0}\right)$. As subspaces of $L^{2}(\partial A)$, the latter reduce the operator $Z$. The restriction of $Z$ to $L^{2}(C)$ is a well-known operator, a so-called bilateral shift (of unit multiplicity). The invariant subspaces of this operator have been extensively studied by Beurling [1], by Helson and Lowdenslager [3], and by Halmos [2]. The restriction of $Z$ to $L^{2}\left(C_{0}\right)$ is a bilateral shift multiplied by the scalar $r_{0}$, and so has the same invariant subspace structure as a bilateral shift. The operator $Z$ is therefore the direct sum of two operators whose invariant subspaces have been completely described. However, the problem of determining the invariant subspaces of $Z$ involves more than merely a routine extension of known results about bilateral shifts, and as yet has not been solved completely.
