primitive forms rather than as loci of corresponding incident elements in polarities, or as loci corresponding to circles in perspectively related forms, thus following the road chosen by Reye rather than that selected by Von Staudt, or Steiner and Cremona.

The book as a whole is full of detail with good sets of exercises after each chapter. The presentation is clear. The method is synthetic for the most part, although the author does not hesitate to use projective coordinates and the resulting analysis somewhat freely throughout the book. For students who wish to pursue geometry beyond the ordinary undergraduate curriculum in our American universities, Professor Amodeo's book will be both suggestive and inspiring.

L. WAYLAND DOWLING

The preparation of this volume marks an important advance in the study of vital statistics in the United States.

The work is divided into eight parts. Part I gives a nontechnical description and explanation of life table functions. Part II gives 74 mortality tables based on different subclasses of the population of registration states. Part III gives twelve life tables of foreign countries and ten mortality tables based on experiences of life insurance companies. Part IV presents graphs of life table functions. Part V gives certain life annuities, life insurance premiums and commutation columns. Part VI gives the mathematical theory of the construction of life tables. Part VII gives a detailed account of the process of carrying out the calculations. Part VIII gives tables of the original statistics and an explanation of the different types of data.

The many tables presented in this volume are simply a mine of information for comparative purposes. Part VI on the mathematical theory of the construction of life tables is the part of the work which should prove of much interest to the actuaries interested in the fundamental theory of life table construction. The reviewer believes it correct to say that pages 329–344 give the first clear and detailed statement in the English language of the theory of the continuous flow of population, with applications to the concrete problems of life table construction. The development of these methods centers around the names of Knapp, Zeuner, and Lexis. The author has done an important service in bringing a clear presentation of these methods before American actuaries. In this theory the aggregates of the living and the dead corresponding to assigned birth and age intervals are derived in terms of definite integrals, and the rates of mortality are obtained as the solution of a linear differential equation. The results are made concrete by application to census data.
