

## Rational Chebyshev Approximations for the Inverse of the Error Function

By J. M. Blair, C. A. Edwards and J. H. Johnson

**Abstract.** This report presents near-minimax rational approximations for the inverse of the error function  $\operatorname{inverf} x$ , for  $0 \leq x \leq 1 - 10^{-10000}$ , with relative errors ranging down to  $10^{-23}$ . An asymptotic formula for the region  $x \rightarrow 1$  is also given.

**1. Introduction.** The inverse error function  $\operatorname{inverf} x$  occurs in the solution of nonlinear heat and diffusion problems [1]. It provides exact solutions when the diffusion coefficient is concentration dependent, and may be used to solve certain moving interface problems. The percentage points of the normal distribution, which are important in statistical calculations, are expressible in terms of  $\operatorname{inverf} x$ , and a common method of computing normally distributed random numbers [2], [3] requires efficient approximations.

The basic mathematical properties of the related function  $\operatorname{inverfc} x$  are discussed in [4] and [1], and 10S Chebyshev series expansions are given in [1]. [5] lists 3D rational approximations, and [6] contains 7S rational minimax approximations to  $\operatorname{inverf} x$  and  $\operatorname{inverfc} x$ . The most accurate set of approximations is given in [7], which contains Chebyshev series expansions accurate to at least 18S for  $0 \leq x \leq 1 - 10^{-300}$ .

This report gives near-minimax rational approximations for  $\operatorname{inverf} x$  for  $0 \leq x \leq 1 - 10^{-10000}$ , with relative errors ranging down to  $10^{-23}$ . An asymptotic series is developed which gives at least twenty-five digits of accuracy over the remaining part of the range  $1 - 10^{-10000} \leq x < 1$ . Tables 1-88 computed by this method are included in the microfiche section of this issue. These tables provide the most efficient representations available, and the low order approximations should be useful in normal random number generators.

**2. Functional Properties.** The error function is defined for all real values of the argument  $y$  by

$$x = \operatorname{erf} y = 2\pi^{-1/2} \int_0^y e^{-t^2} dt$$

and is an odd function of  $y$ . For  $y \geq 0$ ,  $x$  lies in the range  $[0, 1)$ . The complementary error function is defined as

$$\operatorname{erfc} y = 1 - \operatorname{erf} y.$$

The inverse error function is defined by

Key words and phrases. Rational Chebyshev approximations, inverse error function, minimal Newton form.

$$y = \operatorname{inverf} x,$$

and the inverse error function complement by

$$y = \operatorname{inverfc}(1 - x).$$

$\operatorname{inverf} x$  exists for  $x$  in the range  $-1 < x < 1$  and is an odd function of  $x$ , with a MacLaurin expansion of the form

$$\operatorname{inverf} x = \sum_{n=1}^{\infty} C_n x^{2n-1}.$$

The first two hundred values of  $C_n$  are listed in [7].

By inverting the standard asymptotic series

$$(1) \quad \operatorname{erf} y \sim 1 - \frac{\pi^{-1/2}}{y} e^{-y^2} \left[ 1 + \sum_{m=1}^{\infty} (-1)^m \frac{1 \cdot 3 \cdot 5 \cdots (2m-1)}{(2y^2)^m} \right], \quad y \rightarrow \infty,$$

we can derive an asymptotic expansion for  $\operatorname{inverf} x$  of the form

$$(2) \quad \begin{aligned} (\operatorname{inverf} x)^2 &\sim \eta - \frac{1}{2} \ln \eta + \eta^{-1} \left( \frac{1}{4} \ln \eta - \frac{1}{2} \right) \\ &\quad + \eta^{-2} \left( \frac{1}{16} \ln^2 \eta - \frac{3}{8} \ln \eta + \frac{7}{8} \right) \\ &\quad + \eta^{-3} \left( \frac{1}{48} \ln^3 \eta - \frac{7}{32} \ln^2 \eta + \frac{17}{16} \ln \eta - \frac{107}{48} \right) \\ &\quad + \eta^{-4} \left( \frac{1}{128} \ln^4 \eta - \frac{23}{192} \ln^3 \eta + \frac{29}{32} \ln^2 \eta - \frac{31}{8} \ln \eta + \frac{1489}{192} \right) \\ &\quad + \dots, \quad x \rightarrow 1, \end{aligned}$$

where  $\eta = -\ln [\pi^{1/2}(1-x)]$ .

**3. Generation of Approximations.** Rational minimax approximations to  $\operatorname{inverf} x$  were computed in twenty-nine decimal arithmetic on a CDC 6600 using a version of the second algorithm of Remes due to Ralston [8]. The relative error of the approximations was levelled to three digits.

The approximation forms and intervals are

$$\begin{aligned} \operatorname{inverf} x &\simeq xR_{lm}(x^2), & 0 \leq x \leq 0.75, \\ &\simeq xR_{lm}(x^2), & 0.75 \leq x \leq 0.9375, \\ &\simeq \xi^{-1}R_{lm}(\xi), & 0.9375 \leq x \leq 1 - 10^{-100}, \\ &\simeq \xi^{-1}R_{lm}(\xi), & 1 - 10^{-100} \leq x \leq 1 - 10^{-10000}, \end{aligned}$$

where  $R_{lm}(x)$  is a rational function of degree  $l$  in the numerator and  $m$  in the denominator, and where  $\xi = [-\ln(1-x)]^{-1/2}$ .

The auxiliary variable  $\xi$  is necessary in the higher ranges to allow high accuracy approximations with rational functions of reasonable degree. The form of the asymptotic expansion (2) might suggest  $\xi^{-1}R_{lm}(\xi^2)$  as a more natural approximating function. This form was checked, in addition to  $\xi^{-1}R_{lm}(\xi)$  and  $\xi^{-1}R_{lm}(\xi^{1/2})$  for the highest

range of  $x$ , and the latter found to be the most efficient. However, the improvement in accuracy is not enough to offset the cost of the additional square root evaluation.

For the range  $0 \leq x \leq 0.9975$  the master routine computes  $\operatorname{inverf} x$  by solving the equation  $\operatorname{erf} y - x = 0$  by the Newton-Raphson technique. For larger values of  $x$ , in the range  $0.9975 \leq x \leq 1 - e^{-625}$ , we solve instead the equation  $\operatorname{erfc} y - (1 - x) = 0$ . The computation of  $\operatorname{erf} y$  and  $\operatorname{erfc} y$  is based on the algorithm in [9], which was programmed in FORTRAN in 29S arithmetic on a CDC 6600. For  $x > 1 - e^{-625}$  underflow occurs in evaluating  $1 - x$ , and the equation is rewritten as  $\xi(-\ln \operatorname{erfc} y)^{1/2} - 1 = 0$ , where  $\xi = [-\ln(1 - x)]^{-1/2}$ . Newton-Raphson iteration is again used, starting with  $y = 1/\xi$ , and the asymptotic formula (1) is used to compute  $\operatorname{erfc} y$ . Because of the algorithms used, the computed values of  $\operatorname{inverf} x$  and  $\operatorname{inverfc} x$  are expected to be accurate to almost full-working precision.

The master routine was checked by comparing the results against the published formulae of Strecok [7]. The maximum relative differences for the ranges  $[0, 0.8]$ ,  $[0.8, 0.9975]$ ,  $[1 - 25 \times 10^{-4}, 1 - 5 \times 10^{-16}]$ , and  $[1 - 5 \times 10^{-16}, 1 - 10^{-300}]$  are  $0.67 \times 10^{-24}$ ,  $0.13 \times 10^{-22}$ ,  $0.45 \times 10^{-22}$ , and  $0.39 \times 10^{-22}$ , respectively, which are consistent with the magnitudes of the coefficients of the last terms retained by Strecok in his series expansions.

Additional checks consisted of a comparison of the results on either side of the transition points 0.9975 and  $1 - e^{-625}$ , a comparison between the master routine and (2) at  $x = 1 - 10^{-10000}$ , and differencing of the values generated by the master routine. The results indicate that the master routine is accurate to at least twenty-seven digits.

**4. Results.** The details of the approximations are given in Tables 1–88, in a format similar to that used in [10]. Tables 1–4 summarize the best approximations in the  $L_\infty$  Walsh arrays of the function, and Tables 5–88 give the coefficients of selected approximations.

The precision is defined as

$$-\log_{10} \max_x \left| \frac{f(x) - R_{lm}(x)}{f(x)} \right|,$$

where  $f(x)$  is the function being approximated, and the maximum is taken over the appropriate interval.

For the ranges  $[0, 0.75]$  and  $[0.75, 0.9375]$  the rational functions are ill-conditioned, both in the power polynomial and Chebyshev polynomial forms and lose up to three significant digits by cancellation. To eliminate the cancellation the numerator and denominator were subsequently converted to minimal Newton form (MNF) [11], and the resulting coefficients rounded off by an algorithm similar to that described in [10]. For each of the approximations in the tables the MNF has a particularly simple form, being a polynomial in  $(x - x_R)$ , where  $x_R$  is the right-hand end of the approximation interval; and hence, the MNF is no more costly to evaluate than the power polynomial form.

The approximations in Tables 5–88 were verified by comparing them with the master routine for 5000 pseudorandom values of the argument in each interval.
