Boundary Value Techniques for Initial Value Problems in Ordinary Differential Equations

By A. O. H. Axelsson and J. G. Verwer

Abstract. The numerical solution of initial value problems in ordinary differential equations by means of boundary value techniques is considered. We discuss a finite-difference method which was already investigated by Fox in 1954 and Fox and Mitchell in 1957. Hereby we concentrate on explaining the fundamentals of the method because for initial value problems the boundary value method seems to be fairly unknown. We further propose and discuss new Galerkin methods for initial value problems along the lines of the boundary value approach.

1. Introduction. Traditionally, methods used for the numerical integration of initial value problems in ordinary differential equations

\[ \dot{y}(x) = f(x, y(x)), \quad a \leq x \leq b, y(a) \text{ given}, \]

are step-by-step methods. Familiar step-by-step methods, which are also called forward-step methods, are the Runge-Kutta and linear multistep method (see, e.g., Henrici [12], Lambert [16], Stetter [23]). The latter, in its most simple form, is defined by the so-called k-step formula

\[ \sum_{j=0}^{k} \alpha_j y_{n+j} = h \sum_{j=0}^{k} \beta_j f(x_{n+j}, y_{n+j}), \quad \alpha_j, \beta_j, h \in \mathbb{R}, h > 0, k \in \mathbb{N}_+, \]

where \( y_{n+j} \) represents the approximation to the exact solution value \( y(x_{n+j}) \) defined by (1.1). The positive real \( h \) is called the step size. Assuming that \( h \) is constant, it is given by \( h = (b - a)/N \), \( N \) being some positive integer. The points \( x_{n+j} \) are called grid points and belong to the uniform grid

\[ G_h = \{ x_j; x_j = a + jh, j = 0(1)N \}. \]

In the forward-step approach, the numerical solution is obtained by stepping through this grid in the direction from \( a \) to \( b \), i.e., given approximations \( y_{n+j} \) for some integer \( n \) and \( j = 0(1)k - 1 \), the approximation \( y_{n+k} \) at the next grid point \( x_{n+k} \) is computed by solving (1.2) for \( y_{n+k} \). In fact, all results on convergence and numerical stability which emanate from the pioneering work of Dahlquist [5] are based on this forward-step application.
In this paper we will tackle the numerical solution of (1.1) in a completely different way than in the step-by-step approach. For its numerical solution we will consider (1.1) as a two-point boundary value problem with a given value at the left endpoint and an implicitly defined value, by the equations \( \dot{y}(x) = f(x, y(x)) \), at the right endpoint. In this approach formula (1.2) ought to be considered as a finite-difference formula as is the practice in the numerical solution of genuine two-point boundary value problems for systems of first-order differential equations (see Keller [14], [15]). One of the aims of this boundary value approach is to circumvent the known Dahlquist-barriers on convergence and stability which are a direct consequence of the step-by-step application of (1.2). In this respect boundary value methods for (1.1) bear a relationship with the iterative algorithms of Cash [4] for the stable solution of recurrence relations and with Olver’s algorithm [18], [19].

Up to now, boundary value methods for initial value problems have hardly been discussed in the numerical literature. Perhaps because the step-by-step application of formulas of type (1.2) is invariably easier to perform. As far as we know, the first contributions have been made by Fox [9] in 1954 and Fox and Mitchell [10] in 1957. They discuss a simple finite-difference formula for (1.1) and for the derived second-order equation

\[
(1.4) \quad \dot{y}(x) = g(x, y(x)) = \frac{\partial f}{\partial x}(x, y(x)) + \frac{\partial f}{\partial y}(x, y(x))f(x, y(x)).
\]

A feature of the boundary value method is that all approximations on the grid \( G_h \) are generated simultaneously. In 1964 Axelsson [1] proposed a quadrature type method for the integrated form of (1.1) which also computes all approximations over the interval \([a, b]\) simultaneously. This method has been called a global integration method. It is best characterized as a huge implicit Runge-Kutta method which performs just one step with step size \( b - a \). A special feature of this global method is that the global errors at the end of the interval are particularly small, even when the problem is mathematically unstable. On the other hand, the errors of step-by-step methods have a tendency to grow, owing to accumulation at every step, especially when the problem itself is unstable.

Two recent contributions on boundary value methods for initial value problems are due to Rolfes [20] and Rolfes and Snyman [21]. They consider a finite-difference method which has also been proposed by Fox [9] and apply it to stiff equations. Rolfes and Snyman report that the finite-difference method performs satisfactorily on stiff problems. Fox considered nonstiff equations, but was not satisfied with the method because of an oscillating error behavior which prevents the application of difference correction for improving the accuracy.

The present contribution consists of two parts. The first part deals with finite-difference methods, while the second one is devoted to Galerkin methods. When discussing boundary value techniques for initial value problems it is, of course, obvious to consider Galerkin methods because of their use in the numerical solution of genuine two-point boundary value problems. We shall comment on a relation between the two approaches.

To a certain extent this paper is of an expository nature, especially in its first part on finite-difference methods (Section 2). There, we have concentrated on describing
the fundamentals of the boundary value approach, because for initial value problems this approach seems to be fairly unknown. For that purpose Section 2 reports on a case study of a straightforward combination of the explicit midpoint rule with the first-order backward difference formula. Among others, this case study clearly reveals that with respect to stability, an essential difference exists between the standard forward-step and the boundary value approach. We emphasize that the phenomena involved are typical for the boundary value approach, rather than accidental for our case study.

Finally, we should like to mention three serious applications of the boundary value method in situations where the forward-step method may be less appropriate (not further treated in the present paper). Firstly, the numerical solution of initial value problems where the right-hand side function \( f(x, y) \) is not available in analytic form but merely in the form of discrete data.* Such a situation frequently arises in simulation processes. These problems might be tackled by fitting the data so as to generate functions which can be evaluated anywhere such that Runge-Kutta methods or multistep methods can be applied. This approach involves the difficulty of avoiding too large errors in the generated functions. An alternative is to employ a method which uses only the discrete data available. Shampine [22] examines such a method. The boundary value methods of this paper can also be applied to the problems discussed by Shampine [22].

The second application we have in mind lies in the control of the global error. When integrating in a forward-step manner, direct global error control cannot be theoretically justified since the behavior of the global error in time depends on the stability of the problem and on all previous global errors. The only justifiable procedure here is simply reintegration over the whole integration interval with a smaller step size, in case the estimation of the global error has turned out to be too crude. By its very nature, the boundary value method is better adapted for global error control, because now the numerical solutions are computed simultaneously as if we were solving a boundary value problem. This implies that, for global error control purposes, one could implement sophisticated adaptive mesh techniques from currently available boundary value codes.

Thirdly, the boundary value methods can also be used as step-by-step methods but with much larger steps than for an ordinary step-by-step method. A possible application of this is for ill-posed problems of the form (1.1). If the solution to such a problem is smooth, one may approximate it well by a boundary value technique using large time steps, and the inherent instability will not be noticed as much as for an ordinary step-by-step method. This situation is similar to the effect of using parallel shooting instead of just simple shooting in boundary value problems.

Naturally we can also envision problems where a boundary value technique would be less appropriate. This occurs, for instance, in certain nonlinear problems where the solution suddenly becomes very unsmooth. In a step-by-step method one can more easily adapt the step-lengths in order to better approximate the steep gradients when they occur.

---

*This application has been brought to our attention by Larry F. Shampine.

2.1. Outline of the Method. Consider the initial value problem (1.1). Let us discretize the differential equation \( \dot{y} = f(x, y) \) on the grid (1.3) by means of the explicit midpoint rule

\[
y_{n+1} - y_{n-1} - 2hf(x_n, y_n) = 0.
\]

When we apply (2.1) as a step-by-step method we need two initial values, one at the left endpoint \( x = a \), and one at \( x = a + h \). The first initial value is known from the problem, while the second one has to be computed by another method. When we apply (2.1) as a boundary value method it is applied at each of the points \( x_n \in \mathcal{G}_h \) for \( n = 1(1)N - 1 \). In addition to the initial value at the left endpoint \( x = a \), we now need a boundary condition at the right endpoint \( x = b \). For that purpose, one can use the most simple backward-difference formula (Backward Euler)

\[
y_N - y_{N-1} - hf(x_N, y_N) = 0.
\]

Thus we arrive at the discrete boundary value problem

\[
y_0 \text{ given,}
\]

\[
y_{n+1} - y_{n-1} - 2hf(x_n, y_n) = 0, \quad n = 1(1)N - 1, \\
y_N - y_{N-1} - hf(x_N, y_N) = 0,
\]

whose solution values \( y_1, \ldots, y_N \) must be generated simultaneously. Since \( f \) may be nonlinear in \( y \), the discrete problem (2.3) must be solved by iteration. A Newton-type iteration is feasible because of the tridiagonal structure (block-tridiagonal for systems).

As an alternative for formula (2.2), we mention the more accurate trapezoidal rule

\[
y_N - y_{N-1} - \frac{1}{2}hf(x_{N-1}, y_{N-1}) - \frac{1}{2}hf(x_N, y_N) = 0,
\]

or the second-order backward-difference formula

\[
y_N - \frac{2}{3}y_{N-1} + \frac{1}{3}y_{N-2} - \frac{2}{3}hf(x_N, y_N) = 0.
\]

The use of (2.4) or (2.5) instead of (2.2) does not increase the order of accuracy of the method. Both combinations are of order two. Normally, method (2.3) will be somewhat less accurate. Convergence questions are further discussed in Section 2.3.

Combination (2.1), (2.5) has already been proposed by Fox [9] and Fox and Mitchell [10]. Rolfes [20] and Rolfes and Snyman [21] have applied this combination to stiff problems. A slight disadvantage is that by using (2.5), the tridiagonal coupling is lost. This might be overcome, however, by eliminating \( y_{N-2} \) from (2.5) and the particular equation

\[
y_N - y_{N-2} - 2hf(x_{N-1}, y_{N-1}) = 0.
\]

This yields

\[
y_0 \text{ given,}
\]

\[
y_{n+1} - y_{n-1} - 2hf(x_n, y_n) = 0, \quad n = 1(1)N - 1, \\
\frac{2}{3}(y_N - y_{N-1}) - \frac{2}{3}hf(x_{N-1}, y_{N-1}) - \frac{2}{3}hf(x_N, y_N) = 0,
\]

which is just method (2.1), (2.4).

Finally we observe that methods like (2.3) can be directly applied to problems with periodic solutions. The last line of (2.3) then should read \( y_N = y_0 \). In what follows we concentrate on the pure initial value problem.
2.2. The Test Model. In this section we consider the standard test model
\begin{equation}
\dot{y} = \delta y, \quad \delta \in \mathbb{C}, \ a \leq x \leq b, \ y(a) \text{ given.}
\end{equation}
We observe that this model plays an important role in the stability of step-by-step integration methods. The notion of absolute stability (see, e.g., [16]) is based on this simple problem which is also very suitable for becoming acquainted with the boundary value approach and for comparison with the step-by-step approach. In Section 2.3 the model is linked with a constant-coefficient linear system. We will concentrate on method (2.3), i.e., explicit midpoint combined with Backward Euler.

Our discrete boundary value problem (2.3) now reads
\begin{equation}
\begin{aligned}
y_0 &= y(a), \\
y_{n+1} - y_n - 2zy_n &= 0, \\y_N - y_{N-1} - zy_N &= 0,
\end{aligned}
\end{equation}
i.e., we have to solve the linear algebraic system
\begin{equation}
A(z) Y = R,
\end{equation}
where \( Y = [y_1, \ldots, y_N]^T \), \( R = [y(a), 0, \ldots, 0]^T \) and \( A(z) \) is given by
\begin{equation}
A(z) = \begin{pmatrix}
-2z & 1 & & \\
-1 & -2z & 1 & \\
& & \ddots & \ddots & \ddots \\
& & & -1 & -2z & 1 \\
& & & & -1 & 1 - z
\end{pmatrix}.
\end{equation}
The first question which arises is, for which \( z \)-values is \( Y \) a well-defined vector of approximations \( y_n \) to \( e^{\alpha x} y(a), \ n = 1, \ldots, N \), i.e., for which \( z \)-values is \( A(z) \) regular. In what follows, we call \( z \) a regular point for \( A(z) \) if \( A(z) \) is regular. Otherwise, \( z \) is called a singular point.

Define \( \tilde{A}(z) = \text{diag}(1, \ldots, 1, 2) A(z) \), and write \( \tilde{A}(z) = E - 2zI \), i.e.
\begin{equation}
E = \begin{pmatrix}
0 & 1 & & \\
-1 & 0 & 1 & \\
& & \ddots & \ddots & \ddots \\
& & & -1 & 0 & 1 \\
& & & & -2 & 2
\end{pmatrix}.
\end{equation}
\( A(z) \) is singular, iff \( \tilde{A}(z) \) is singular. Hence we can use \( \tilde{A}(z) \), and in turn the constant matrix \( E \) to find the singular points for \( A(z) \). Obviously, the location of the eigenvalues \( \lambda_j \) of \( E \) is decisive, since \( z \) is a singular point, iff \( z = \lambda_j / 2 \).

**Lemma 1.** All eigenvalues \( \lambda_j \) of \( E \) satisfy \( 0 < \text{Re}(\lambda_j) \leq 2, -2 \leq \text{Im}(\lambda_j) \leq 2 \).

**Proof.** The inequality \(-2 \leq \text{Im}(\lambda_j) \leq 2 \) is a direct consequence of Geršgorin’s circle theorem. To prove the inequality for the real part we first perform the similarity transformation
\begin{equation}
\tilde{E} = \text{diag}(1, \ldots, 1, d) E \text{ diag}(1, \ldots, 1, d^{-1})
\end{equation}
which leaves the spectrum invariant. Let \( \lambda \) and \( \mu \) be the real and imaginary parts of an arbitrary eigenvalue and let \( u \) and \( v \) be the real and imaginary parts of the corresponding eigenvector. Then we easily derive
\begin{equation}
\frac{1}{2} [u^T (\tilde{E} + \tilde{E}^T) u + v^T (\tilde{E} + \tilde{E}^T) v] = \lambda (u^T u + v^T v).
\end{equation}
Now we take \( d = 1/\sqrt{2} \) for which \( \frac{1}{2}(\tilde{E} + \tilde{E}^T) = \text{diag}(0, \ldots, 0, 2) \). Hence,
\[
0 < \frac{1}{2}u^T(\tilde{E} + \tilde{E}^T)u \leq 2u^Tu, \quad \text{all } u \in \mathbb{R}^N,
\]
so that \( 0 < \lambda < 2 \). Finally, assume \( \lambda = 0 \) and let \( u_i, v_i \) denote the \( i \)th component of \( u \) and \( v \), respectively. From (2.13) it then follows that \( u_N = v_N = 0 \). By using the relations \( \tilde{E}u = -\mu v, \tilde{E}v = \mu u \) and the specific form of \( \tilde{E} \) it is now easy to verify that \( u_i = v_i = 0 \), all \( i = 1(1)N \). This leads to a contradiction, showing that \( \lambda \neq 0 \). \( \square \)

We thus have the following result:

**Theorem 2.** All singular points \( z \) for \( A(z) \) satisfy \( 0 < \text{Re}(z) \leq 1, -1 \leq \text{Im}(z) \leq 1 \).

We cannot determine the eigenvalues of \( E \) explicitly. Note that if in \( E \) the last row elements are replaced by \(-1\) and \(0\), respectively, the eigenvalues become \( 2i \cos(j\pi/(N + 1)), j = 1(1)N \). Figure 1 shows all numerically computed eigenvalues of \( E \) and \( E/2h \) for some values of \( h = N^{-1} \). The eigenvalues of \( E/2h \) play an important role in the convergence analysis (cf. Section 2.3). We see that when \( N \) increases, a pair of eigenvalues of \( E \) approaches \( \pm 2i \). This means that for \( N \) large, the points \( \pm i \) will act numerically as singular points for \( A(z) \).

The second question we now wish to discuss is, how well are the decaying exponentials \( e^{nz} \) approximated. From diagonal dominance properties it easily follows that for \( \text{Re}(z) \ll 0 \) (stiff eigenvalues) \( |y_n| \) is an excellent approximation to \( |e^{nz}y(a)| \). More precisely, if \( z \neq 0 \) is a regular point, then (2.10) can be rewritten as
\[
Y = -(2z)^{-1}(I - (2z)^{-1}Ey)^{-1}R, \quad \text{which implies}
\]
\[
y_1 = -(2z)^{-1}y(a) + O(|z|^2), \quad y_n = O(|z|^2), \quad n = 2(1)N, \quad |z| \to \infty.
\]
Observe that the method cannot approximate positive exponentials if \( \text{Re}(z) \gg 0 \). Roughly speaking, for \( |\text{Re}(z)| \) large, the approximations for the negative and positive exponential \( e^{nz} \) are of the same magnitude.

To get more insight into the question of how decaying exponentials are approximated, we now proceed with the analytical solution of the recurrence equation
\[
y_{n+1} - y_{n-1} - 2zy_n = 0 \quad \text{defined by the explicit midpoint rule when applied to test-model (2.8)}:
\]
\[
y_n = C_1\mu_1^n + C_2\mu_2^n, \quad n = 1, 2, \ldots, N,
\]
where \( \mu_1 = z + \sqrt{z^2 + 1}, \mu_2 = z - \sqrt{z^2 + 1} \) and \( C_1, C_2 \) are constants to be determined by boundary conditions. Note that \( \mu_1 = e^z + O(z^3) \), \( z \to 0 \), whereas \( \mu_2 \) has no relation to \( e^z \), i.e. \( \mu_2 \) is the parasitic root.

Solution (2.14) can be adapted to our discrete problem (2.9) via \( C_1 \) and \( C_2 \) by requiring
\[
C_1 + C_2 = y(a),
\]
\[
(1 - z)(C_1\mu_1^N + C_2\mu_2^N) = C_1\mu_1^{N-1} + C_2\mu_2^{N-1}.
\]
Solving for \( C_1 \) and \( C_2 \) yields
\[
C_2 = \delta C_1, \quad C_1 = y(a)/(1 + \delta), \quad \text{where}
\]
\[
\delta = \left( \frac{-1}{\mu_2^2} \right)^{N-1}\eta, \quad \eta = \frac{1 - \mu_1(1 - z)}{(1 - z)\mu_2 - 1},
\]
where
\[
\mu_2 = z - \sqrt{z^2 + 1}.
\]
and where it is assumed that \( \text{Re}(\delta) \neq -1 \). \( \text{Re}(\delta) = -1 \) means singularity of the \( 2 \times 2 \) system (2.15). Like for system (2.10), one thus must distinguish singular and regular points \( z \). We emphasize that the set of singular points for (2.15) is not identical with that of \( A(z) \). For example, \( z = \pm i \) is a singular point for (2.15) for all \( N \), but not for \( A(z) \) according to Theorem 2. Nevertheless, as observed before, for numerical computations, the points \( z = \pm i \) must be regarded also as singular points for \( A(z) \). Of course, if \( z \) is a singular point for \( A(z) \) and not for (2.15), (2.14) defines a particular solution for system (2.10).

Let us consider the behavior of the principal solution component \( C_1 \mu_1^n \) and the parasitic component \( C_2 \mu_2^n \) for varying \( n \) and \( z \), where we restrict ourselves to \( z \leq 0 \) and \( N \) even. We observe that for \( N \) even, \( z \in \mathbb{R} \), the quantity \( \delta \geq 0 \), since \( \eta(0) = 0 \) and \( \eta(z) < 0 \) if \( z \neq 0 \). Hence, for \( z \leq 0 \) and \( N \) even, the solution (2.14) is well-defined and is just the unique solution of system (2.10).

We distinguish between \( z = 0 \) and \( z < 0 \). The case \( z = 0 \) corresponds to \( y(x) = 0 \), i.e., \( y(x) = y(a) \), \( a \leq x \leq b \). It is readily seen that for \( z = 0 \), \( y_n = y(a) \) for all \( n = 1, \ldots, N \). Hence the constant solution is computed without error. For \( z < 0 \), i.e., decaying exponentials, we have \( 0 < \mu_1 < 1, \mu_2 < -1 \) and the limit behavior

\[
\begin{align*}
\mu_1 &\sim 1 + z, \quad \mu_2 \sim -1 + z, \quad \eta \sim -\frac{1}{4}z^2 \quad \text{as } z \uparrow 0, \\
\mu_1 &\to 0, \quad \mu_2 \to -\infty, \quad \eta \sim -\frac{1}{4}z^{-2} \quad \text{as } z \to -\infty.
\end{align*}
\]

Taking this into consideration, the behavior of \( C_1 \mu_1^n \) and \( C_2 \mu_2^n \) is best described as follows. \( C_1 \mu_1^n \) approximates the decaying solution for \( z \) close to zero and vanishes if \( z \to -\infty \). This is true for all \( 1 \leq n \leq N \). For \( z \) close to zero, the parasitic component \( C_2 \mu_2^n \) is negligibly small (up to the discretization order in \( z \)). For \( h \) fixed, \( C_2 \mu_2^n \) increases with \( n \). However, for all \( z < 0 \), its contribution to \( y_n \) is negligible for all \( n, \ 1 \leq n \leq N \). We once more note that for \( \text{Re}(z) < 0 \) (stiff eigenvalues) the strongly decaying exponential \( e^{nz} \) is well approximated. A similar description can be given for \( z > 0 \).

At this point it is appropriate to make a comparison with the standard step-by-step approach. Suppose that the explicit midpoint rule is applied that way. Consider the general solution (2.14). In order to obtain absolute stability \( \mu_1 \) and \( \mu_2 \) now must satisfy the root condition, i.e., none of the characteristic roots has modulus greater than one and every root with modulus one is simple. The root condition is satisfied if and only if \( z \) is purely imaginary and \( |z| < 1 \). Hence, as is well-known, the step-by-step explicit midpoint rule has no real interval of absolute stability, which shows that with respect to stability the boundary value method is just opposite to the step-by-step method. In fact, from the investigation of equations (2.14)-(2.16), it can be seen that the boundary value method can be applied for \( \text{Re}(z) < 0 \), just because there \(|\mu_1| < 1 \) and \(|\mu_2| > 1 \). This conclusion, which is valid for other difference schemes as well, has been drawn before by Rolfes [20]. She considers the tridiagonal infinite Toeplitz matrix with rows \((-1 \ 0 \ 1)\) and shows that the forward-backward substitution of the \( LU \)-decomposed Toeplitz matrix can be interpreted as a stable forward recursion (\(|\mu_1| < 1 \)) followed by a stable backward recursion (\(|\mu_2| > 1 \)) (see also [18], [19]).
2.3. Convergence Properties. This section is devoted to convergence properties of the finite-difference boundary value method. As in the preceding section we concentrate on method (2.3). It will be assumed that the vector function \( f: [a, b] \times \mathbb{R}^5 \rightarrow \mathbb{R}^5 \) is as smooth as our analysis requires.

We introduce the conventional operators \( \mathcal{N} \) and \( \mathcal{N}_h \) (see, e.g., [14], [15]):

\[
\mathcal{N} y = y(x) - f(x, y(x)) = 0, \quad a \leq x \leq b, \quad y(a) \text{ given},
\]

\[
\mathcal{N}_h y_n = \frac{y_{n+1} - y_{n-1}}{2h} - f(x_n, y_n) = 0, \quad n = 1, \ldots, N - 1, \quad y_0 = y(a), \quad y_N = y(b),
\]

Next, for any sufficiently smooth function \( v(x) \), we define the local truncation errors \( \tau_n[v] = \mathcal{N}_h v(x_n) - \mathcal{N} v(x_n), n = 1(1)N, \) and observe that

\[
\tau_n[0] = \frac{1}{2} h^2 \delta v(x_n) + O(h^3), \quad n = 1(1)N - 1,
\]

\[
\tau_N[v] = -\frac{1}{2} h \delta v(x_n) + O(h^2).
\]

Let \( e_n \) be the global error vector at \( x_n \), i.e., \( e_n = y_n - y(x_n), n = 1(1)N \). By subtracting \( \mathcal{N}_h y(x_n) \) from \( \mathcal{N}_h y_n \) and by using the mean value equation

\[
f(x_n, y(x_n) + e_n) - f(x_n, y(x_n)) = M(x_n) e_n,
\]

\[
M(x_n) = \int_0^1 f'(x_n, y(x_n) + \theta e_n) \, d\theta, \quad f'(x, u) = \frac{\partial f}{\partial u}(x, u),
\]

it can be seen that \( e_n \) satisfies the difference scheme

\[
\mathcal{L}_h e_n = \frac{e_{n+1} - e_{n-1}}{2h} - M(x_n) e_n = -\tau_n[y], \quad n = 1(1)N - 1,
\]

\[
\mathcal{L}_h e_N = \frac{e_N - e_{N-1}}{h} - M(x_N) e_N = -\tau_N[y],
\]

where \( e_0 \) is the zero vector and \( y = y(x) \) denotes the exact solution of the initial value problem (1.1). Hence method (2.3) is convergent, for a given vector function \( f \), if for this function \( \mathcal{L}_h \) is a stable difference operator (cf., [14], [15]).

Let us reformulate (2.17) in the block matrix form

\[
\begin{pmatrix}
-2hM(x_1) & I \\
-I & -2hM(x_2) & I \\
& \ddots & \ddots & \ddots \\
& & -I & -2hM(x_{N-1}) & I \\
& & & -I & - hM(x_N) \\
\end{pmatrix}
\begin{pmatrix}
\frac{1}{h} \tau_1[y] \\
\frac{1}{h} \tau_2[y] \\
\vdots \\
\frac{1}{h} \tau_{N-1}[y] \\
\frac{1}{h} \tau_N[y] \\
\end{pmatrix}
= \begin{pmatrix}
e_1 \\
e_2 \\
\vdots \\
e_{N-1} \\
e_N \\
\end{pmatrix}
\]

which we denote by

\[
\mathcal{A}_h \bar{e} = (E_1 \otimes I - 2h \mathcal{M}) \bar{e} = -2h \bar{\tau},
\]
where $E_1$ is given by (2.12) with the last row divided by two, and where $\otimes$ denotes
the direct matrix product. The definitions of $M$, $\tilde{e}$, and $\tilde{r}$ are obvious. Stability of $L_h$
is equivalent to the existence and uniform boundedness of the inverses of the family of
matrices $h^{-1}S_h$.

Example 3. To gain some feeling for how the local errors $\tau_n$ accumulate in the
global error we now first consider the scalar equation $\dot{y}(x) = f(x)$, i.e., $f$ does not
depend on $y$. Then $\tilde{e}$ satisfies

\begin{equation}
(2h)^{-1}E_1 \tilde{e} = -\tau.
\end{equation}

From the computation of $E_1^{-1}$ one finds the global errors

\begin{equation}
\begin{aligned}
e_n &= -\sum_{j=1}^{n/2} 2h\tau_{2j-1}, \quad n \text{ even,} \\
e_n &= e_{n-1} - \sum_{j=n}^{N} 2h(-1)^{j-1}\tau_j + h(-1)^{N-1}\tau_N, \quad n \text{ odd, } e_0 = 0.
\end{aligned}
\end{equation}

It follows that for all $n$, $e_n = O(h^2)$. Note that $\tau_N = O(h)$ occurs only once in each
$e_n$, $n$ odd, and not in $e_n$ if $n$ is even. We also see a distinction between even and odd
numbered errors, implying that $e_n$ is not smooth when considering all grid points.

In Example 3 we considered an over-simplified problem. It nicely illustrates,
however, the role of the matrix $E$, or $E_1$, in the convergence process, which, as we
will show below, plays a similar role for the general problem.

Let us proceed with Eq. (2.19). Since $E_1$ is nonsingular, we can write

\begin{equation}
(I - 2h(E_1^{-1} \otimes I)M)\tilde{e} = \tilde{r},
\end{equation}

Note that we use $I$ to denote the $s \times s$ unit matrix, as well as the $sN \times sN$
unit matrix. The $sN$-vectors $\tilde{r}$ and $\tilde{y}$ consist of $N$ blocks, each of length $s$. Let $\tilde{r}_j$ and
$\tilde{y}_j$ denote the $N$-vector composed of the $j$th element from each block. These vectors are
associated with the $j$th component of the solution vector $y(x)$. Then, for $j = 1(1)s$,
we have $(2h)^{-1}E_1\tilde{y}_j = -\tilde{r}_j$ as in Eq. (2.20), implying that each $n$th element of $\tilde{y}_j$
satisfies relation (2.21). This in turn implies that each element of the whole vector $\tilde{y}$
is $O(h^2)$, or, equivalently,

\begin{equation}
\|\tilde{r}\|_\infty \leq C h^2, \quad C \text{ a constant not depending on } h \leq h_0.
\end{equation}

\textbf{Theorem 4.} Let $\|M(x)\|_\infty \leq \frac{1}{2}$ for all $x \in [a, b]$. Then method (2.3) is convergent
in the maximum norm with order two.

\textbf{Proof.} Consider Eq. (2.22) and observe that $hE_1^{-1} \otimes I$ is uniformly bounded. In
fact, from the equation for $e_1$ in (2.21) it follows that $\|hE_1^{-1} \otimes I\|_\infty = 1$. The proof is
now easily completed by applying the perturbation lemma to the left-hand side
matrix of Eq. (2.22) and by using inequality (2.23). \qed

This result covers only a rather narrow class of problems on account of the norm
inequality on $M(x)$. For example, stiff problems do not satisfy this inequality. The
above derivation indicates, however, through the introduction of $\tilde{y}$, that for the
general problem $\dot{y} = f(x, y)$, the global errors show a similar behavior as described
in Example 3. In fact, we observed this behavior in all our numerical experiments,
with nonstiff, as well as stiff problems. In the next theorem we will prove convergence in the spectral norm for a much broader class of problems:

**Theorem 5.** Define

\[
\mu_2(f'(x, u)) = \max_i \lambda_i \left( \frac{f'(x, u) + f'^T(x, u)}{2} \right),
\]

where \( \lambda_i(\cdot) \) denotes the \( i \)-th eigenvalue and assume that \( \mu_2(f'(x, u)) \leq \nu < 0 \) for all \((x, u) \in [a, b] \times \mathbb{R}^s\). Method (2.3) is then convergent in the spectral norm.

**Proof.** We consider the matrix \( A^*_h = (-2h)^{-1} A_h \) (cf. (2.19)). By definition,

\[
\mu_2(A^*_h) = \max_i \lambda_i \left( \text{diag} \left( \frac{M_1 + M_1^T}{2}, \ldots, \frac{M_N - 1 + M_N^T - 1}{2}, \frac{-2I + h(M_N + M_N^T)}{4h} \right) \right),
\]

where \( M_n = M(x_n) \). For all \( h > 0 \) we have

\[
\mu_2(A^*_h) \leq \max_n \mu_2(M_n) \leq \nu.
\]

The first inequality is trivial, while the second is a direct consequence of the definition of \( M_n \) and of a result given by Dahlquist [5, p. 11]. Since \( \nu < 0 \) does not depend on \( h \), but only on the problem, and since

\[
\max_i \lambda_i(A^*_h) \leq \mu_2(A^*_h),
\]

it is immediate that \( A^*_h^{-1} \) exists and is uniformly bounded in \( \| \cdot \|_2 \). More precisely,

\[
\|A^*_h^{-1}\|_2 \leq -\nu^{-1}, \text{ so that }
\]

\[
(2.24) \quad \|e\|_2 \leq -\nu^{-1}\|\tilde{y}\|_2. \quad \Box
\]

We observe that the method of proof of this theorem cannot be used to deal with Eq. (2.22). This prevents us from proving order two convergence in the spectral norm. In Section 3, however, we are able to prove second-order convergence in the spectral norm by considering method (2.3) as a particular Galerkin method.

The inequality \( \mu_2(f'(x, u)) \leq \nu < 0 \) is satisfied by all differential equations which possess strictly contractive solutions in the Euclidean vector norm (see Dahlquist [5, p. 13] and [6, Chapter 2]). Hence Theorem 5 covers a broad and interesting class of problems, including many stiff ones. Furthermore, for these problems the stiffness, i.e., the magnitude of the stiff eigenvalues of \( f'(x, u) \), does not enter into the one-sided Lipschitz constant \( \nu \). This constant \( \nu \) is related to the smooth, nonstiff solution components (see [6, Chapter 2] for a clarifying discussion). Inequality (2.24) thus shows that if the solution to be computed is smooth, the global error will not suffer from the stiffness of the problem. Rolfs and Snyman [20], [21] observed this in their experiments.

If \( \nu \) is very close to zero, inequality (2.24) is useless. We emphasize, however, that the algorithm then still may perform quite satisfactorily, even if \( \nu \) is larger than zero. We will explain this from the constant-coefficient linear model system

\[
(2.25) \quad \dot{y}(x) = My(x) + g(x), \quad M \text{ a normal matrix, } M = XDX^{-1}.
\]
Consider for (2.25) the matrix $A_h$ given by (2.18), but with the last row again multiplied by two. We then can write $A_h^* = (2h)^{-1}A_h$ in the form

$$A_h^* = \left( I \otimes X \right) \left( \frac{E \otimes I}{2h} - I \otimes D \right) \left( I \otimes X^{-1} \right),$$

$E$ as in (2.12). The eigenvalues of $A_h^*$ are the $sN$ numbers (cf. [17, p. 259])

$$\lambda_j/2h - \delta_k, \quad j = 1(1)N, \quad k = 1(1)s,$$

where $\lambda_j$ and $\delta_k$ are the eigenvalues of $E$ and $M$, respectively (each eigenvalue $\delta_k$ of $M$ plays the role of $\delta$ in the test-model (2.8)). Hence method (2.3) will perform satisfactorily on problem (2.25), for a certain $h$, if the eigenvalues (2.26) stay away from zero. Figure 1 shows all numerically computed eigenvalues of $E/2h$ for some values of the step size $h$. Note that some of the eigenvalues remain close to the imaginary axis if $h$ decreases. Further, $\max \Re(\lambda_j/2h)$ slowly increases as $h$ decreases. Figure 1 is useful to ascertain for which spectra of $M$ the method will converge. For example, if $M$ has positive eigenvalues $\delta_k$, i.e., the problem is unstable: the method will perform satisfactorily for $h < h_0$ if $\max \delta_k < \max \Re(\lambda_j/2h_0)$. See also Fox and Mitchell [10], where it is pointed out that boundary value methods may have an advantage over step-by-step methods if the problem to be integrated is unstable.

*Figure 1*

Eigenvalues of $E$ (left plot) and $E/2h$ (right plot) for $h = \frac{1}{16}, \frac{1}{32}, \frac{1}{64}$. We have only plotted eigenvalues with nonnegative imaginary part.
2.4. *A Numerical Illustration.* This section deals with a numerical example which serves to illustrate the convergence results derived in the previous section. For that purpose we selected the simple scalar problem

\[(2.27) \quad \dot{y}(x) = \delta \left( y(x) - \frac{1}{x + 1} \right) - \frac{1}{(x + 1)^2}, \quad 0 \leq x \leq 1, y(0) = 1, \delta \in \mathbb{R}, \]

whose general solution is given by \( y(x) = e^{\delta x} (y(0) - 1) + 1/(x + 1). \) Since \( y(0) = 1, \) only the smooth solution component \( 1/(x + 1) \) has to be computed. If \( \delta \ll -1, \) \((2.27)\) is an example of a stiff problem where \( e^{\delta x} y(0) \) represents the strongly varying solution component. In order to give sufficient insight into the error behavior, which has been predicted in Example 3, results will be shown for various choices of \( h \) and \( \delta. \) We wish to emphasize that these results are not isolated. On the contrary, in a qualitative sense they are valid for systems as well. We refer to [20], [21] for extensive experiments with a known collection of stiff problems.

Table 2 contains results of method (2.3) for \( h = 1/4, 1/8, 1/16, \) and \( \delta = -1, -5, -10, -100. \) Table 3 shows results for \( \delta = 1, 5, 10, 100. \) The following observations are relevant. The lack of smoothness over the grid is clearly observable. However, when we consider either even grid points, or odd ones, the error behaves smoothly. Recall that we only have to compute the smooth solution of (2.27). For \( \delta < 0 \) the algorithm nicely shows its order two convergence at even-numbered grid points. Observe that after halving \( h \) the absolute error should decrease by a factor 4 because the method is of order two and that \(-\log_{10}(1/4) = 0.6.\) At odd grid points the order behavior is much less pronounced as expected from Example 3. For \( \delta > 0 \) the algorithm yields more or less comparable results, though the second order not always shows up. This is because \( \delta \) comes too close to the spectrum of \( E/2h \) (cf. Figure 1).

3.1. Preliminaries. We consider nonlinear systems of ODE's

\[(3.1) \quad \dot{U} = \tilde{F}(t, U), \quad 0 < t \leq T, U(\cdot) \in \mathbb{R}^n, U(0) \text{ prescribed.}\]

We first make a transformation of this equation to a more suitable form. In problems to be considered, there may exist positive stiffness parameters $\epsilon_i$, such that parts of $\tilde{F}$ and the corresponding parts of the Jacobian matrix $\partial \tilde{F}/\partial U$ are unbounded as $O(\epsilon^{-1})$, $\epsilon_i \to 0$. We then multiply the corresponding equations by this parameter to get

\[(3.2) \quad \epsilon \dot{U} = F(t, U), \quad 0 < t \leq T,\]

where $\epsilon$ is a diagonal matrix with entries $\epsilon_i, 0 < \epsilon_i \leq 1$, and $F$ and $\partial F/\partial U$ are bounded with respect to $\epsilon$. A typical example is given by $\tilde{F}(t, U) = \tilde{A}U + \tilde{C}$

\[
\tilde{A} = \begin{pmatrix}
-1800 & 900 & \cdot & \cdot \\
1 & -2 & 1 & \cdot \\
\cdot & \cdot & \cdot & \cdot \\
1 & -2 & 1 & \cdot \\
1000 & -2000 & \cdot & \cdot
\end{pmatrix}, \quad \tilde{C} = \begin{pmatrix}
0 \\
0 \\
\vdots \\
0 \\
1000
\end{pmatrix}
\]

found in Enright et al. [8]. Here $\epsilon = \text{diag}(\frac{1}{900}, 1, \ldots, 1, \frac{1}{1000})$ is an obvious choice. In more general problems we may have to multiply by a more general positive-definite matrix $\epsilon$, in order to get a bounded $F$ and $\partial F/\partial U$. We further assume that $F$ satisfies

\[(3.3) \quad (F(t, U) - F(t, V), U - V) \leq \rho(t)\|U - V\|^2 \quad \forall U, V \in \mathbb{R}^n, t > 0,\]
where \( \rho: [0, T] \to \mathbb{R} \) is at least piecewise continuous and independent of \( e \) and \( \rho(t) \leq -\rho_0, \ t \geq t_0 \geq 0, \rho_0 > 0 \). Further \( \|V\| = (V, V)^{1/2} \), where \((\cdot, \cdot)\) is the inner product in \( \mathbb{R}^m \). As is well-known and easily seen, this means that, if \( U, V \) are two solutions of (3.2) corresponding to different initial values, then

\[
\frac{1}{2} \frac{d}{dt} (e(U - V), U - V) = (F(t, U) - F(t, V), U - V) \\
\leq \rho(t)\|U - V\|^2 \\
\leq \rho(t) (e(U - V), U - V), \quad t \geq t_0,
\]

so

\[
\|U(t) - V(t)\|^2 \leq \exp\left( \int_{t_0}^t 2\rho(s) \, ds \right) \|U(t_0) - V(t_0)\|^2 \\
\leq \|U(t_0) - V(t_0)\|^2, \quad t_0 \leq t \leq T,
\]

where \( \|V\|_e = (eV, V)^{1/2} \). This means that the system is contractive for \( t \geq t_0 \) if condition (3.3) holds. We further assume that \( F \) is Lipschitz continuous, i.e., there exists a constant \( C \) such that

\[
(3.4) \quad \|F(t, U) - F(t, V)\| \leq C\|U - V\| \quad \forall U, V \in \mathbb{R}^m.
\]

In the initial phase \((0, t_0)\), the system does not have to be contractive, i.e., the eigenvalues of the Jacobian may have positive real parts. In this interval we may choose to use a step-by-step method with very small step sizes, if it is of importance to follow the transients.

### 3.2. The Galerkin Method

We first describe the global Galerkin method to be used in the interval \((t_0, T)\). We divide this interval into a number of subintervals \((t_{i-1}, t_i)\), \( i = 1, 2, \ldots, N \), where \( t_N = T \). The length of the intervals, \( t_i - t_{i-1} \), may vary smoothly with some function \( h(t_i) \), but for ease of presentation, we assume that the intervals have equal length, i.e., \( t_i - t_{i-1} = h, i = 1, 2, \ldots, N \). We consider each interval as an element on which we place some nodal points, \( t_{i,j}, j = 0, 1, \ldots, p \), and \( t_{i,j} = t_i + \xi_j h \), where \( \xi_j \) are the Lobatto quadrature points which satisfy \( 0 = \xi_0 < \xi_1 < \cdots < \xi_p = 1 \), and \( \xi_j + \xi_{p-j} = 1 \). Hence the endpoints of the interval are always nodal points and (if \( p > 1 \)) we choose also \( p - 1 \) disjoint nodal points in the interior of each element.

To each nodal point we associate a basis function \( \phi_{i,j} \). The basis functions may be exponential or trigonometric functions and may also be discontinuous, but in this paper we only consider the most common choice where they are continuous and polynomials over each element. Basis functions corresponding to interior nodes have support only in the element to which they belong, and those corresponding to endpoints have support over the two adjacent elements (except those at \( t_0 \) and at \( t_N \)). The number of nodal points in each closed interval then equals the degree \( p \) of the polynomial plus one.

Let \( \hat{S}_h \) be the subspace of test functions which are zero at \( t_0 \), i.e.,

\[
\hat{S}_h = \text{SPAN}\{ \phi_{i,j}, i = 0, 1, \ldots, N - 1, j = 1, 2, \ldots, p \}.
\]
Let

\[ a(U; V) \equiv \int_{t_0}^{T} (eU - F(t, U), V) \, dt, \quad U, V \in [H^1(t_0, T)]^m, \]

where \( H^1(t_0, T) \) is the first-order Sobolev space of functions with square-integrable derivatives. To get an approximation \( \bar{U} \) of the solution of (3.2), we take a test function (vectorial function) \( V = \phi_{i,j}^r \), and multiply the equation with \( V \) to get, after integration,

\[ a(\bar{U}; \phi_{i,j}^r) = \int_{t_{i-1}}^{t_i} (e\bar{U} - F(t, \bar{U}), \phi_{i,j}^r) \, dt = 0, \quad j = 0, i = 1, 2, \ldots, N - 1, \tag{3.5a} \]

\[ a(\bar{U}; \phi_{i,j}^r) = \int_{t_i}^{t_{i+1}} (e\bar{U} - F(t, \bar{U}), \phi_{i,j}^r) \, dt = 0, \quad j = 1, 2, \ldots, p - 1, i = 0, 1, \ldots, N - 1. \tag{3.5b} \]

At \( t_N = T \), we get

\[ a(\bar{U}; \phi_{N,0}^r) = \int_{t_{N-1}}^{t_N} (e\bar{U} - F(t, \bar{U}), \phi_{N,0}^r) \, dt = 0. \tag{3.5c} \]

Here we choose in turn \( \phi_{i,j}^r = \phi_{i,j} e_r \), where \( \phi_{i,j} \) is the corresponding scalar basis function and \( e_r \) the \( r \) th coordinate vector. This defines the Galerkin approximation \( \bar{U} \) corresponding to \( \mathcal{S}_h \), where

\[ \bar{U} = U(t_0) \phi_{0,0} + \sum_{i=0}^{N-1} \sum_{j=1}^{p} d_{i,j} \phi_{i,j}, \quad d_{i,j} \in \mathbb{R}^m, \]

i.e., we have imposed the essential boundary condition at \( t_0 \). Clearly,

\[ a(U; V) = 0 \quad \forall V \in [H^1(t_0, T)]^m. \]

We then get from (3.5a)

\[ a(U; V) - a(\bar{U}; V) = \int_{t_{i-1}}^{t_i} (e[U - \bar{U}] - [F(t, U) - F(t, \bar{U})], V) \, dt = 0, \tag{3.6} \]

\[ V = \phi_{i,j}^r, j = 0, i = 1, 2, \ldots, N - 1, r = 1, 2, \ldots, m, \]

and similarly for (3.5b, c).

To estimate the Galerkin discretization error \( U - \bar{U} \), we let \( U_i \in S_h \) be the interpolant to \( U \) on \( \{t_{i,j}\}, j = 0, 1, 2, \ldots, p, i = 0, 1, \ldots, N - 1 \), and we write

\[ U - \bar{U} = \eta - \theta, \]

where \( \eta = U - U_i \) is the interpolation error and

\[ \theta = -U + \bar{U} + \eta = \bar{U} - U_i. \]
Note that $\theta \in \mathcal{S}_h$. Assuming that the solution $U$ is sufficiently smooth, from the interpolation error expansion in integral form we get the usual Sobolev norm estimates

$$
\int_{t_0}^T \|U - U_j\|^2 dt \leq C_0 h^{2(p+1)} \int_{t_0}^T \|U\|_{p+1}^2 dt,
$$

(3.7)

$$
\int_{t_0}^T \|\dot{U} - \dot{U}_j\|^2 dt \leq C_1 h^{2p} \int_{t_0}^T \|\ddot{U}\|_{p+1}^2 dt,
$$

for the interpolation error. Here,

$$
\|U\|_{p+1}^2 = \int_{t_0}^T \sum_{k=0}^{p+1} \left( \frac{\partial^k U}{\partial t^k}, \frac{\partial^k U}{\partial t^k} \right) dt
$$

is the norm in the Sobolev space $H^{p+1}(t_0, T)$.

**Theorem 6.** Let $U$ be the solution of (3.2) where (3.3), (3.4) are satisfied. Then the Galerkin solution $\hat{U}$, in the space of piecewise polynomial continuous functions of degree $p$, defined by (3.5a, b, c) satisfies

$$
\|U - \hat{U}\| = O(h^{p+\nu}) \left\{ \|eU\|_{p+2}^2 + \|U\|_{p+1}^2 \right\}^{1/2}, \quad h \to 0,
$$

where $\nu = 1$ if $p = 1$, $1 > \nu > \frac{1}{2}$ if $p = 3, 5, \ldots$ and $\nu = 0$ if $p$ is even, and

$$
\|V\| = \frac{1}{2} \left\{ \langle eV(T), V(T) \rangle - \int_{t_0}^T \rho(t) \|V(t)\|^2 dt \right\}.
$$

(Note that this estimate implies both a least-square estimate as well as a pointwise estimate at the endpoint of the interval.)

For a proof, see [3].

3.3. Difference Schemes. In order to get a fully discretized scheme we have to use numerical quadrature, which results in various difference schemes. We shall consider this only for the case $p = 1$. Then $\phi_{i,p} = \phi_i$ are the usual hat functions and there are no interior nodes. With

$$
\hat{U} = U(t_0)\phi_0 + \sum_{i=1}^N U_i \phi_i,
$$

(3.5a) and (3.5c) imply

$$
\begin{aligned}
\varepsilon(\hat{U}_{i+1} - \hat{U}_{i-1}) &= 2 \int_{t_{i-1}}^{t_i} F(t, \hat{U}_{i-1}\phi_{i-1} + \hat{U}_i\phi_i + \hat{U}_{i+1}\phi_{i+1})\phi_i dt, \\
\varepsilon(\hat{U}_N - \hat{U}_{N-1}) &= \int_{t_{N-1}}^{t_N} F(t, \hat{U}_{N-1}\phi_{N-1} + \hat{U}_N\phi_N)\phi_N dt.
\end{aligned}
$$

(3.8)

We call this the generalized midpoint rule difference scheme. Let $F_i = F(t, \hat{U})|_{t=t_i}$. If we use numerical integration by the trapezoidal rule, i.e.,

$$
\int_{t_{i-1}}^{t_i} F\phi_i dt = \frac{1}{2} h \left[ F_{i-1}\phi_i(t_{i-1}) + F_i\phi_i(t_i) \right] = \frac{1}{2} h F_i,
$$

We have the following estimate for $p = 1$:

$$
\|U - \hat{U}\| = O(h^2) \left\{ \|eU\|_2 + \|U\|_1 \right\}^{1/2}, \quad h \to 0,
$$

where $\|\cdot\|_p$ denotes the norm in the Sobolev space $H^p(T, \hat{U})$.
we recover the difference method (2.1), (2.2). As we know, this scheme is of $O(h^2)$, see Section 2.3. We consider now a more accurate difference scheme which we may derive from (3.8). For this purpose let

$$F(t) = \frac{1}{2} \left[ F_{i-1} + F_i \right] + \left( t - t_i + \frac{h}{2} \right) \frac{1}{h} (F_i - F_{i-1}), \quad t_{i-1} \leq t \leq t_i,$$

except that for the last formula in (3.8) we use

$$F(t) \approx \frac{1}{2} \left[ F_{N-1} + F_N \right], \quad t_{N-1} \leq t \leq t_N.$$

Then

$$\int_{t_{i-1}}^{t_i} F(t) \phi_i \, dt = \frac{h}{4} (F_{i-1} + F_i) + \frac{h}{12} (F_i - F_{i-1}) = \frac{h}{6} (F_{i-1} + 2F_i), \quad i = 1,2,\ldots,N-1,$$

and similarly

$$\int_{t_i}^{t_{i+1}} F(t) \phi_i \, dt = \frac{h}{6} (F_{i+1} + 2F_i).$$

Hence, the generalized midpoint rule (3.8) takes the form

$$\left\{ \begin{array}{l}
e(\hat{U}_{i+1} - \hat{U}_{i-1}) = \frac{h}{3} \left( F_{i-1} + 4F_i + F_{i+1} \right), \quad i = 1,2,\ldots,N-1, \\
e(\hat{U}_N - \hat{U}_{N-1}) = \frac{h}{2} (F_{N-1} + F_N) .\end{array} \right.$$ (3.9)

We notice that this is a combination of the Simpson and trapezoidal rules.

For this combination, numerical tests (see Tables 4 and 5) indicate very accurate results. Note that already on a very coarse mesh ($h = \frac{1}{2}$) the accuracy is high. For $\delta < 0$ (Table 4), the order of convergence seems to be $\approx 3.5$.

Finally some remarks about methods for the solution of the algebraic systems. These have block-tridiagonal form. If we use a special starting scheme for the calculation of $\hat{U}_1$, we may use a “shooting method” for the solution of (3.1), i.e.,

$$\hat{U}_{i+1} = \hat{U}_{i-1} + 2hF(t_i, \hat{U}_i), \quad i = 1,2,\ldots.$$

This is, of course, nothing but the two-step midpoint rule, which, as is well-known, is unstable for stiff problems (and of order $O(h^2)$ for nonstiff problems). If the order of the systems (3.1, 3.2) is large and $\partial F/\partial U$ is sparse we may, however, apply an iterative method, which would preserve sparsity. There exist methods, such as preconditioned generalized conjugate gradient methods, for which convergence of the iterations is fast; see, for instance, Axelsson [2], and Hageman and Young [11].

Hence the large size of the matrices which arise should not be detrimental for the application of the methods described in this paper.

From the analyses and the numerical experiments it is concluded that the global method is a robust reliable method for both stiff systems and systems with increasing fundamental solutions. It is particularly efficient when moderate accuracy is desired. It does not seem to be very sensitive to stiffness.
In the case of high accuracy, large or nonlinear systems, the efficiency depends on the availability of good algebraic systems solvers.

Supplement to
Boundary Value Techniques for Initial Value Problems
in Ordinary Differential Equations

By A. O. H. Axelsson and J. G. Verwer

APPENDIX

In [1], the following Theorem 6 was presented for the error of a
Galerkin method for initial value problems. Here we present a proof.

THEOREM. Let $U$ be the solution of (3.2) where (3.3), (3.4) in [1] are
satisfied. Then the Galerkin solution $\bar{U}$, in the space of piecewise polynomial
continuous functions of degree $p$, defined by (3.5a,b,c) in [1] satisfies

$$\| U - \bar{U} \|_{H^{p+1}} \leq O(h^{p+1}) \left\{ \| U \|_{H^{p+1}} + \| U' \|_{H^{p+1}} \right\}, \quad h \to 0,$$

where $\nu = 0$ if $p = 1$, $1 \leq \nu \leq \frac{1}{2}$ if $p = 3, 5, \ldots$ and $\nu = 0$ if $p$ is even, and

$$\| V \|_{H^2} = \frac{1}{2} \left\langle (eV(t), V(t)) \right\rangle + \int_{t_0}^{T} \rho(t) \| V(t) \|^2 dt.$$ 

PROOF. Our first objective is to derive an estimate of $\delta$. We have

$$\theta(t_0) = n(t_0) = 0 \text{ and}$$

$$(1) \quad a(\bar{U}; \theta) = a(U; \theta) = \int_{t_0}^{T} ((\theta, \theta) - (F(t, U) - F(t, U'), \theta)) dt. $$

From

$$\int_{t_0}^{T} (\theta, \theta) dt = - \int_{t_0}^{T} (\theta, \theta) dt + \left[ (\theta, \theta) \right]_{t_0}^{T},$$

if follows that

$$\int_{t_0}^{T} (\theta, \theta) dt = \frac{1}{2} \left\langle (e\theta(t), \theta(t)) \right\rangle.$$ 

Hence by (3.3)，
Further we get from (3.6) and the Lipschitz continuity (3.4), in [1]

\[ a(u, v) - a(u_1, v) = a(u_0, v) - a(u_1, v) + a(u_1, v) - a(u_1, v_0) = 0 + \int_0^T (c(v_0) dt) + C \int_0^T \| v_0 \|^2 dt. \]

First we shall estimate the term \( \int_0^T (c(\varepsilon_0) dt) \). Since \( \varepsilon \) is a diagonal matrix, we may consider each component individually, i.e., \( \int_0^T \varepsilon_0(t) dt \), where \( \varepsilon_0 \) is a scalar function. Since \( \varepsilon_0 \in \mathbb{S}_n^1 \), have

\[ \varepsilon_0 = \sum_{i=0}^{N-1} \sum_{j=1}^p y_{ij} e_i e_j, \]

where \( \{ e_i \} \), \( i = 0, 1, \ldots, N-1 \), \( j = 1, 2, \ldots, p \) is a set of basis functions (test functions) spanning \( \mathbb{S}_n^1 \), but not necessarily equal to \( e_i e_j \). We write \( \varepsilon_0 = \varepsilon_0^P + \varepsilon_0^Q \), where \( \varepsilon_0^P \) is the leading (polynomial) term in an expansion of the interpolation error (for more details, see e.g. Axelsson and Gustafsson [2]). For instance, if we use piecewise linear basis functions, then at \( t_i \), \( i = 1, 2, \ldots, N-1 \) we have

\[ \varepsilon_0(t) = \begin{cases} \tilde{v}_i(t_i)(t-t_{i-1})(t-t_i), & t_{i-1} \leq t \leq t_i \\ \tilde{v}_i(t_i)(t-t_i)(t-t_{i+1}), & t_i \leq t \leq t_{i+1} \end{cases}. \]

(For simplicity, we may assume that \( N \) is even.) With the piecewise polynomial basis functions of degree \( p \), an easy calculation shows that

\[ \int_0^T \varepsilon_0^P dt = 0, \int_0^T \varepsilon_0^Q dt = 0. \]

We shall prove that because of cancellation
We have

\[
\int_0^1 \frac{\tilde{h}_k(\xi)}{\tilde{h}_k(\xi)} \, d\xi = 0
\]

for all \( k \geq 1 \). Hence, if we apply Lobatto quadrature, we get from the error term of the quadrature,

\[
\int_0^1 \frac{\tilde{h}_k(\xi)}{\tilde{h}_k(\xi)} \, d\xi = 0.
\]

The loss of \( p \) in the exponent is due to the fact that

\[
\frac{2^p}{2^{p+1}} \tilde{h}_k(\xi) = 0.
\]

Note however that for \( p \) odd this derivative, which is piecewise \( p \)-th order, appears with the same numerical value but with opposite signs in the two adjacent intervals \((c_{i-1}, c_i)\) and \((c_i, c_{i+1})\). Hence

\[
\int_0^1 \frac{\tilde{h}_k(\xi)}{\tilde{h}_k(\xi)} \, d\xi = 0, i = 0, 1, \ldots, n-1.
\]

and by (7)

\[
\int_0^1 \frac{\tilde{h}_k(\xi)}{\tilde{h}_k(\xi)} \, d\xi = 0.
\]

Consider first the case of piecewise linear basis functions \((p = 1)\). Then we only have one test function at \( \tilde{h}_k \). With \( \tilde{h}_k = \tilde{h}_k(\xi) \), we get

\[
\int_0^1 \frac{\tilde{h}_k(\xi)}{\tilde{h}_k(\xi)} \, d\xi = 0.
\]

License or copyright restrictions may apply to redistribution; see https://www.ams.org/journal-terms-of-use
\[(1)\quad 1 \geq v = \min_{1 \leq k \leq n} v_k \geq \frac{1}{2}.\]

Finally, from (2), (3) and (5) we get
\[
\|v\|^2 \leq O(h^{2(p+v)}|\epsilon|^2 + h^2) + \|h\|^2
\leq O(h^{2(p+v)}|\epsilon|^2 + h^2), \quad p = 1, 3, \ldots.
\]

Clearly, this estimate with \(v = 0\) is also valid for \(p\) even. We now obtain the Galerkin error
\[
\|u - \tilde{u}\| \leq \|u - u_1\| + \|u_1 - \tilde{u}\| = \|h\| + \|\tilde{u}\| \leq 0(h^{p+v})\{\|\epsilon|^2 + h^2\}, \quad h = 0.
\]

Note that if \(U\) is smooth, \(\tilde{U}\) and \(U_1\) will be smooth, so
\[
\int_{t_0}^{T} \frac{\epsilon^2}{h_k} \, dt = \int_{t_0}^{T} \frac{\epsilon^2}{h_k} \, dt = O(h^{-1}).
\]

Hence it follows from (10), (11) that \(v\) will be close to 1.
