A Targeted Martinet Search

Eric D. Driver and John W. Jones

Abstract. Constructing number fields with prescribed ramification is an important problem in computational number theory. In this paper, we consider the problem of computing all imprimitive number fields of a given degree which are unramified outside of a given finite set of primes \( S \) by combining the techniques of targeted Hunter searches with Martinet’s relative version of Hunter’s theorem. We then carry out this algorithm to generate complete tables of imprimitive number fields for degrees 4 through 10 and certain sets \( S \) of small primes.

An important problem in the study of fields is to determine all number fields of a fixed degree having a prescribed ramification structure. This paper will focus on finding all imprimitive number fields of a given degree unramified outside of a finite set of primes.

Hunter’s theorem has been used extensively for computing all primitive number fields of a given degree with absolute discriminant below a given bound. In [13], Martinet gives a version of Hunter’s theorem suitable for relative extensions which has been used to carry out similar searches for imprimitive fields [4, 5, 16, 17, 18, 19]. Note, however, that for even modest degree fields and small sets of primes, such as \( S = \{2, 3\} \), using a standard Hunter search to find all fields unramified outside \( S \) can become computationally burdensome. This can be ameliorated by carrying out a targeted Hunter search where one searches for all fields with specific discriminants, but only those possible for fields unramified away from \( S \). This approach was introduced in [6] and refined in [7] to determine all sextic and septic fields with \( S = \{2, 3\} \), respectively. It has subsequently been used to investigate fields of degrees 8 and 9 ramified at a single prime in [11, 12].

In this paper, we combine Martinet’s theorem with the targeted search technique to form what we call a targeted Martinet search. We then demonstrate the algorithm by using it to compute complete tables of imprimitive decic fields with prescribed ramification.

Section 1 describes the process of conducting a number field search based on Martinet’s theorem. The size of the relative extensions considered in applications here are larger than those in the literature. Section 2 describes how targeting can be used with a search described in Section 1 with details on combining congruences and archimedean bounds given in Section 3. Finally, Section 4 summarizes the results of several searches carried out using the methods in this paper.

1. Martinet’s theorem and Archimedean bounds

If \( K \) is a number field, \( \mathcal{O}_K \) will be its ring of integers and \( d_K \in \mathbb{Z} \) will denote its discriminant. Hermite’s constant for \( j \)-dimensional lattices will be denoted \( \gamma_j \).

A standard approach to computing complete tables of degree \( n \) extensions of \( \mathbb{Q} \) with discriminant \( |d_K| \leq B \) for some bound \( B \) is to use Hunter’s theorem. This approach is only guaranteed to find all primitive extensions, i.e., those with no intermediary fields. We will be interested in imprimitive extensions and will make use of Martinet’s generalization of Hunter’s theorem for relative extensions \[13\].

**Theorem 1** (Martinet). Let \( K \) be a number field of degree \( m \) over \( \mathbb{Q} \) and let \( L \) be a finite extension of \( K \) of relative degree \( n = [L : K] \). Let \( \sigma_1, \ldots, \sigma_m \) denote the embeddings of \( K \) into \( \mathbb{C} \). Then there exists \( \alpha \in \mathcal{O}_L - \mathcal{O}_K \) such that

\[
\sum_{i=1}^{mn} |\alpha_i|^2 \leq \frac{1}{n} \sum_{j=1}^{m} |\sigma_j(\text{Tr}_{L/K}(\alpha))|^2 + \gamma_{m(n-1)} \left( \frac{|d_L|}{n^m |d_K|} \right)^{1/m(n-1)},
\]

where the \( \alpha_i \)'s are the conjugates of \( \alpha \). Furthermore, \( \alpha \) can be chosen arbitrarily modulo addition by elements of \( \mathcal{O}_K \) and also modulo multiplication by roots of unity in \( \mathcal{O}_K \).

We will use the notation in Martinet’s theorem for the remainder of this paper. We also use the standard notation \( T_2(\alpha) := \sum_{i=1}^{mn} |\alpha_i|^2 \).

1.1. Archimedean bounds. Let \( \alpha \in \mathcal{O}_L - \mathcal{O}_K \) be the element given by Martinet’s theorem and let \( f_{\alpha,K}(x) \in \mathcal{O}_K[x] \) be the characteristic polynomial for \( \alpha \) over \( K \). We write

\[ f_{\alpha,K}(x) = x^n + a_1 x^{n-1} + \cdots + a_{n-1} x + a_n \]

where each \( a_i \in \mathcal{O}_K \). If \( \omega_1, \omega_2, \ldots, \omega_m \) is an integral basis for \( K/\mathbb{Q} \), then we may write \( a_i = \sum_{j=1}^{m} a_{ij} \omega_j \) where each \( a_{ij} \in \mathbb{Z} \). When working with \( a_i \) in this basis, we will denote the column vector \((a_{i1}, \ldots, a_{im})^T\) by \( \vec{a}_i \). Note that

\[ \langle \vec{a}_i, \vec{a}_i \rangle = \sum_{j=1}^{m} |\sigma_j(a_i)|^2 \]

is a positive definite quadratic form on \( \vec{a}_i \). Here, we will mainly report on upper bounds for \( \langle \vec{a}_i, \vec{a}_i \rangle \). More details can be found in \[4 \[10 \[16 \[17 \].

For the coefficient \( a_1 \), one can shift the components so that \( -\lfloor \frac{n-1}{2} \rfloor \leq a_{1j} \leq \lfloor \frac{n}{2} \rfloor \) for each \( j \) and \( 0 \leq a_{11} \leq \lfloor \frac{n}{2} \rfloor \). If \( a_{11} \) through \( a_{1k} \) are all zero, we may normalize the next coefficient \( 0 \leq a_{1,k+1} \leq \lfloor \frac{n}{2} \rfloor \). Finally, whenever \( m = 2 \) we observe that any search with a given \( a_1 \) is equivalent to one that uses the Galois conjugate of \( a_1 \), so we may remove any \( a_1 \) from our list of candidates whose Galois conjugate is already on the list. A short table of explicit values for \( a_1 \) can be found in \[10 \] §[2.1] for degree \( [L : \mathbb{Q}] = mn \leq 10 \).

Once the value for \( a_1 \) has been fixed, we have an exact numerical value for Martinet’s bound:

\[ T_2(\alpha) \leq C_{a_1} := \frac{1}{n} \sum_{j=1}^{m} |\sigma_j(a_1)|^2 + \gamma_{m(n-1)} \left( \frac{|d_L|}{n^m |d_K|} \right)^{1/m(n-1)}. \]

It may be possible to replace \( a_1 \) with an equivalent element for which \( \sum_{j=1}^{m} |\sigma_j(a_1)|^2 \) is smaller, and hence gives a more efficient bound \( C_{a_1} \). This improvement
incorporated into Martinet-type searches for nonics in [5]. In the most interesting case here, namely when the base field is quadratic (i.e. \( m = 2 \)), it is not hard to prove that the values for \( a_1 \) given in [10] are already optimal in this regard.

For the constant coefficient \( a_n \), there is a standard bound derived from the arithmetic/geometric mean inequality, yielding

\[
\langle \vec{a}_n, \vec{a}_n \rangle \leq \left( \frac{C_{a_1}}{n} \right)^n.
\]

To bound the other coefficients, we first bound the power sum \( s_k = \sum_{j=1}^{n} |a_j|^k \), and then inductively use Newton’s formula to get bounds on \( a_k \). The power sums \( s_k \) satisfy

\[
\langle \vec{s}_k, \vec{s}_k \rangle \leq C_{a_1}^k.
\]

Given \( a_i \) and \( s_i \) for \( i \in \{1, 2, \ldots, k-1\} \), set \( \vec{b} = -\sum_{j=1}^{k-1} a_{k-j} s_j \). Then the coefficient \( a_k \) satisfies the relation

\[
\vec{a}_k = \frac{1}{k} (\vec{b} - \vec{s}_k).
\]

1.2. The method of Pohst. It is possible to improve the bounds on \( s_k \) when \( k \geq 3 \) based on a method of M. Pohst [15]. Define

\[
T_k := \sum_{j=1}^{n} |a_j|^k,
\]

where the \( a_j \)'s are the roots of \( f_{a,K} \). Clearly, \( |s_k| \leq T_k \). Suppose that \( a_n \) has been fixed and let \( t_2 \) be a bound for \( T_2 \). The method of Pohst uses Lagrange multipliers to minimize the bounds on \( T_k \) (\( 3 \leq k \leq n-1 \)) subject to the constraints that \( \sum_{j=1}^{n} |a_j|^2 \leq t_2 \) and \( \prod_{j=1}^{n} |a_j| = |a_n| \). A more detailed description can be found in [3, p. 458].

In carrying out number field searches based on Martinet’s theorem, there is little need for better bounds on the \( s_k \) when \( n = 2 \) or 3. The only other case in the literature is where \( n = 4 \), in which case Pohst’s theorem is applied to the degree \( mn \) polynomial \( \text{Norm}_{K/Q}(f_{a,K}) \) (see e.g., [17]). Here, the need for good archimedean bounds was more pressing for the \( n = 5 \) cases under consideration. We find it useful to apply Pohst’s theorem to both the degree \( mn \) polynomial and individually to \( f_{a,K} \) and its conjugates. We explain the derivation of the latter bounds below.

For the \( i \)-th conjugate polynomial of \( f_{a,K} \), we define

\[
T_k^{(i)} := \sum_{j=1}^{n} |\sigma_{ij}(\alpha)|^k \quad (1 \leq i \leq m).
\]

In order to get a bound \( t_2^{(f)} \) for \( T_2^{(f)} \), we use the Martinet bound to give us

\[
T_2^{(f)} = \sum_{j=1}^{n} |\sigma_{ij}(\alpha)|^2 \leq C_{a_1} - \sum_{i=1}^{m} \sum_{j=1}^{n} |\sigma_{ij}(\alpha)|^2.
\]

Next, from the arithmetic/geometric mean inequality we have

\[
\sum_{j=1}^{n} |\sigma_{ij}(\alpha)|^2 \geq n \left[ \prod_{j=1}^{n} |\sigma_{ij}(\alpha)|^2 \right]^{1/n} = n |\sigma_i(a_n)|^{2/n}.
\]
Substituting this into \((3)\), we finally get
\[
T_2^{(\ell)} \leq C_n + n \sum_{i=0}^{m} |\sigma_i(a_n)|^{2/n}.
\]

Now let \(t_k^{(i)}\) be the bound for \(T_k^{(i)}\) obtained by applying the method of Pohst to the \(i\)th conjugate polynomial; we then have \(|\sigma_i(s_k)| \leq t_k^{(i)}\). Combining these bounds together we get
\[
\langle \tilde{s}_k, \tilde{s}_k \rangle = \sum_{i=1}^{m} |\sigma_i(s_k)|^2 \leq \sum_{i=1}^{m} \left( t_k^{(i)} \right)^2.
\]

2. Targeting

For the number field \(K\), if \(p\) is a prime ideal of \(\mathcal{O}_K\) we denote the completion of \(K\) by \(K_p\), and \(p\) the prime below \(p\). Then \(\mathcal{O}_p\) will denote the ring of integers of \(K_p\) and \(\mathfrak{P}_p\) the maximal ideal of \(\mathcal{O}_p\). The factorization \(p\mathcal{O}_L\) will be denoted \(\mathfrak{P}_1^{e_1} \cdots \mathfrak{P}_g^{e_g}\) and \(f_i\) will denote the residue field degrees. Notations for completions \(L_p\) are analogous to those for \(K\) described above. Finally, if \(S\) is our set of integral primes, then we let \(S_K\) denote the set of prime ideals of \(\mathcal{O}_K\) which lie above some \(p \in S\).

Fix a prime ideal \(p \in S_K\). Then the decomposition \(p\mathcal{O}_L = \mathfrak{P}_1^{e_1} \cdots \mathfrak{P}_g^{e_g}\) corresponds to the decomposition of the local algebra
\[
L \otimes_K K_p \cong \prod_{i=1}^{g} L_{\mathfrak{P}_i}.
\]

At the finest level, a local target for \(p\) can be a candidate for \(L \otimes_K K_p\), a separable degree \(n\) algebra over \(K_p\). For practical reasons, we typically consider larger targets. For the searches in Section 1 our targets consisted of unordered collections of triples \((e_i, f_i, c_i)\) representing the ramification indices, residue field degrees, and discriminant exponents of the extensions \(L_{\mathfrak{P}_i} / K_p\). Note, however, that in all cases, a local target provides sufficient information to determine the \(\mathfrak{P}\)-part of \(d_L\). Combining this for all primes dividing \(d_K\) and primes in \(S\) gives \(d_L\) for applying Martinet’s theorem. Then, larger targets, such as all extensions where the relative extension is unramified outside \(S\), can then be searched by searching a series of smaller targets.

As in Section 1 \(f_{\alpha,K}\) denotes the characteristic polynomial of \(\alpha\) over \(K\) where \(L = K(\alpha)\). Then \(f_{\alpha,K}\) factors into irreducibles over \(\mathcal{O}_{K_p}\) as \(f_{\alpha,K} = h_1 \cdots h_g\) which correspond to the factorization of \(L \otimes_K K_p\) in equation (1). Moreover, since \(\alpha\) is integral over \(\mathcal{O}_K\), each \(h_i\) has coefficients in \(\mathcal{O}_{K_p}\). For congruences derived from this factorization, we note that for all \(k\), we have \(f_{\alpha,K} \equiv h_1 \cdots h_g \pmod{p^k}\) where we may take each \(h_i \in \mathcal{O}_K[x]\) because \(\mathcal{O}_K\) is dense in \(\mathcal{O}_{K_p}\). The basic process is to simply compute congruences for the \(h_i\) modulo \(p^k\), and then multiply these polynomials to obtain congruences for \(f_{\alpha,K}\) modulo \(p^k\).

Let \(\Gamma \subseteq \mathcal{O}_K\) be a complete set of representatives for \(\mathcal{O}_K/p\) with \(1 \in \Gamma\). Then we immediately have
\[
h_i \equiv r_i^{e_i} \pmod{\mathfrak{P}_{K_p}}
\]
where \(r_i\) is a degree \(f_i\) monic polynomial with coefficients in \(\Gamma\). 

License or copyright restrictions may apply to redistribution; see https://www.ams.org/journal-terms-of-use
For tamely ramified primes, equation (6) suffices. When the ramification is wild, however, the congruences given by equation (5) can be improved significantly by working modulo a power of \( \mathcal{P}_K \). We use Ore congruences as in [7]. We illustrate the general situation with an example.

Consider the case of a cubic extension where we have \( e = p = 3 \) and \( f = 1 \). Let \( \rho \) be a uniformizer for \( K_p \), and let \( \pi \) be a uniformizer for \( L_p \). Let \( e_0 \) be the ramification index of \( \mathcal{P}_K \) over \( \mathbb{Z}_p \), so that \( \nu_\pi(p) = 3e_0 \). The minimal polynomial for \( \pi \) over \( K_p \) is Eisenstein, so it can be written
\[
f_\pi(x) = x^3 + \rho k_1 A x^2 + \rho k_2 B x + \rho C \in K_p[x],
\]
where \( A, B, C \in \mathcal{O}_K \). If we let \( d \) denote the exponent of \( \mathcal{P}_L \) in \( D(L_p/K_p) \), then
\[
d = \nu_\pi(f_\pi'(\pi)) \\
= \nu_\pi(3\pi^2 + 2\rho k_1 A \pi + \rho k_2 B) \\
= \min\{\nu_\pi(3\pi^2), \nu_\pi(2\rho k_1 A \pi), \nu_\pi(\rho k_2 B)\} \\
= \min\{3e_0 + 1, 3k_1 + 1, 3k_2 + 1\}.
\]
It is easy to see that we can always take \( 1 \leq k_1 \leq k_2 \leq e_0 + 1 \). Thus, we would work modulo \( \rho^{k_2} \).

The coefficients of the characteristic polynomial for any \( \beta \in \mathcal{P}_L \) will satisfy the same divisibility conditions as the coefficients of \( f_\pi \); and any element \( \beta \in \mathcal{O}_L \) is a translate by some \( \gamma \in \Gamma \) of an element in \( \mathcal{P}_L \). Therefore, the corresponding local factor \( h_i \) will take the form
\[
h_i = (x + \gamma)^3 + \rho k_1 A(x + \gamma)^2 + \rho k_2 B(x + \gamma) + \rho C \\
\equiv (x + \gamma)^3 + \rho k_1 A(x + \gamma)^2 + \rho C \pmod{\mathcal{P}_K^{k_2}}
\]
for some \( A, B, C \in \mathcal{O}_K \) and some \( \gamma \in \Gamma \). We then write \( A \) and \( C \) as power series in \( \rho \) with coefficients from \( \Gamma \) to obtain explicit congruences.

3. Algorithm implementation

The bounds derived earlier take the form
\[
\langle \bar{a}, \bar{a} \rangle \leq B
\]
for a positive definite quadratic form \( \langle , \rangle \) where \( B \) is a positive real number and the column vector \( \bar{a} = (a_1, \ldots, a_m)^T \in \mathbb{Z}^m \) represents the element \( a = \sum_{i=1}^m a_i \omega_i \) which is either a polynomial coefficient or a power sum.

Explicitly, if \( Q = [\sigma_i(\omega_j)]_{ij} \), then \( \langle \bar{a}, \bar{a} \rangle = \bar{a}^T Q \bar{a} \) where \( Q^H \) denotes the conjugate transpose of \( Q \) and \( \bar{a}^T \) is simply the transpose of \( \bar{a} \). Since \( \bar{a} \in \mathbb{Z}^m \) and \( \langle \bar{a}, \bar{a} \rangle \) are real, let \( A \) be the matrix of real parts of \( Q^H Q \), and our bound (6) becomes \( \bar{a}^T \bar{a} \leq B \).

To get efficient bounds on the components of \( \bar{a} \), we use the Cholesky decomposition of the quadratic form associated to \( A \) as in [2], section 2.7.3. In our applications, the lattice has very small dimension, so we used a simple approach to enumerating short vectors in the lattice. With larger lattices, one might use Fincke-Pohst instead.

Now, suppose we want to find elements \( a = \sum_{i=1}^m a_i \omega_i \in \mathcal{O}_K \) which are congruent to \( c = \sum_{i=1}^m c_i \omega_i \in \mathcal{O}_K \) modulo the ideal \( \mathfrak{a} \). The ideal \( \mathfrak{a} \) is a free \( \mathbb{Z} \)-module of rank
where \( k \) for some \( m \).

Each \( \mu_j \) may be written \( \mu_j = \sum_{i=1}^{m} \mu_{ij} \omega_i \), where \( \mu_{ij} \in \mathbb{Z} \). We choose our basis for \( \mathbf{a} \) so that the matrix \( M = (\mu_{ij}) \) is in Hermite normal form.

Now if \( a \equiv c \pmod{\mathbf{a}} \), then \( a - c \in \mathbf{a} \) which implies
\[
\sum_{i=1}^{m} a_i \omega_i - \sum_{i=1}^{m} c_i \omega_i = k_1 \mu_1 + \cdots + k_m \mu_m
\]
for some \( k_i \in \mathbb{Z} \). Equating the coefficients of the \( \omega_i \)'s, we get the following matrix equation:
\[
\tilde{a} = M \tilde{k} + \tilde{c}.
\]

Now define \( \tilde{k}' = \tilde{k} + M^{-1} \tilde{c} \). Then
\[
\tilde{a} = M(\tilde{k}' + M^{-1} \tilde{c}) = M \tilde{k}'.
\]

We now use the bound on \( \tilde{a} \) to give bounds on the \( k_i \)'s. From equation 66 we get
\[
(QM)^T (QM) \tilde{k}' \leq B.
\]

As before, there exists an auxiliary matrix \( A \) such that \( (\tilde{k}')^T A \tilde{k}' \leq B \) and \( A \) is a positive definite real symmetric matrix. Using the Cholesky decomposition for \( A \) we can enumerate small vectors \( \tilde{k}' \), i.e., those satisfying \( (\tilde{k}', \tilde{k}')_A \leq B \) for the positive definite quadratic form given by \( A \). If we write these bounds as \( L_i' \leq k_i' \leq U_i' \), then we get the following bounds on the \( k_i \)'s,
\[
[L_i' - c_i'] \leq k_i \leq [U_i' - c_i']
\]
where \( \tilde{c}' = M^{-1} \tilde{c} \). We will write these bounds as \( L_i \leq k_i \leq U_i \). Note that the bounds \( L_i \) and \( U_i \) depend on the current values of \( k_{i+1}, \ldots, k_m \). So to obtain all values for \( \tilde{k} \), we first loop over the range for \( k_m \). The current value for \( k_m \) is used to get looping bounds for \( k_{m-1} \). Then the current values for \( k_m \) and \( k_{m-1} \) are used to get looping bounds for \( k_{m-2} \), and so on.

The search algorithm loops over all combinations of the \( k_i \)'s, and for each combination, computing \( \tilde{a} = M \tilde{k} + \tilde{c} \). Observe that the bounds on the \( k_i \)'s are smaller than the bounds on the \( a_i \)'s so that the search region has been reduced. This is analogous to the one-dimensional case where one considers all elements \( a \) such that \( a = c + kp \) (here \( \mu_1 = p \) is the modulus of the congruence vector). If the archimedean bounds are \( |a| < B \), then \( k = \frac{a - c}{p} \) so that \( \frac{B - c}{p} \leq k \leq \frac{B - c}{p} \).

The above method is modified slightly when the bound is on a power sum instead of a polynomial coefficient. Suppose we are interested in the \( j \)th \((2 \leq j \leq n-1)\) polynomial coefficient and we have the following bound on the \( j \)th power sum:
\[
\langle s_j, s_j \rangle \leq B.
\]

From Newton’s formula, we may write
\[
ja_j = \tilde{b}_j - s_j
\]
where \( \tilde{b}_j = - \sum_{i=1}^{j-1} a_{j-i} s_i \in \mathbb{Z}^m \).
If we define
\[ \vec{c}':= \frac{1}{j} \left( \vec{b}_j - j \vec{c} \right) \]
and
\[ \vec{k}' := \vec{c}' - \vec{k}, \]
then we have
\[ \vec{s}_j = \vec{b}_j - j \vec{a}_j \]
\[ = \vec{b}_j - j (M \vec{k} + \vec{c}) \]
\[ = jM \left[ \frac{1}{j} M^{-1}(b_j - j \vec{c}) - \vec{k} \right] \]
\[ = j M \vec{k}'. \]

The bound on \( \vec{s}_j \) can now be used to get a bound on \( \vec{k}' \):
\[ \langle \vec{s}_j, \vec{s}_j \rangle = \langle j M \vec{k}', H Q H Q (j M \vec{k}') \rangle = j^2 \langle \vec{k}', (QM)^H (QM) \vec{k}' \rangle \]
\[ \implies \langle \vec{k}', \vec{k}' \rangle_{QM} = \frac{1}{j^2} \langle \vec{s}_j, \vec{s}_j \rangle \leq \frac{B}{j^2}. \]

As before, there exists an auxiliary matrix \( A \) such that \( \langle \vec{k}', \vec{k}' \rangle_A \leq \frac{B}{j^2} \) and \( A \) is a positive definite real symmetric matrix. The rest of the algorithm remains the same.

4. Applications

The targeted Martinet search was used to construct complete tables of imprimitve number fields with prescribed ramification. We did this for degrees 4, 6, 8, 9, and 10; the results of which can be found on our websites \[8, 9\]. The algorithm was programmed in \( C \) using the pari library \[14\].

The web site \[8\] contains results of Hunter searches for sextic fields which were known to be complete for all Galois groups except for \( \text{C}_2 \cdot 3, \text{C}_4 \) and \( \text{C}_2 \cdot \text{D}_4 \). In \[9\], the search for sextic fields with \( S = \{2, 3\} \) was shown complete for these groups by class field theory. Using the methods of this paper, the tables were proven complete for 33 other values of \( S \).

In this section, we consider the specific case of degree 10 fields unramified outside the set \( S = \{2, 3\} \). The search was done in two parts. The first part did a search for quadratic extensions of a quintic base field, and the second part searched for quintic extensions of a quadratic base field.

The results of our quadratic over quintic search are summarized in Table\[1\] where the fields are sorted by Galois group. Searches involving quadratic extensions are inherently easier than quintic extensions. This is a relatively simple computation, so we completed this search in two ways, by targeted Martinet searches as described above, and by class field theory. We note that computing quadratic extensions of quintic fields by Martinet searches has appeared previously in the literature (see \[18, 19\]). Class field theory is especially easy to apply in this situation because it just entails taking square roots of the appropriate elements of quintic fields. This is simplified further by the fact that we are allowing ramification above 2, and that the 6 quintic base fields all have narrow class number one. This search took roughly 1.5 hours by a targeted Martinet search and 10 seconds by class field theory using a script written for \textit{gp} \[14\].
Table 1. All decics unramified outside $S = \{2, 3\}$ and having a quintic subfield.

Table 2 gives the results for the much more difficult quintic over quadratic search. The data is sorted vertically by quadratic base field, and horizontally by Galois group. The results are complete for all 7 of the quadratic base fields which are unramified outside $\{2, 3\}$. Run times for the first 6 base fields varied from 25 hours for the $\mathbb{Q}(\sqrt{-3})$ case to 30 days for the $\mathbb{Q}(\sqrt{2})$ case. Run times are heavily dependent on the discriminant of the base field. For the last base field $\mathbb{Q}(\sqrt{6})$, we decided to use a distributed computing approach using BOINC \[1\]. We found a dozen volunteer host machines, including a dual Clovertown (8 cores) and a pair of quad-core Xeon servers. The $\mathbb{Q}(\sqrt{6})$ case was finally settled after about 60 days of hard-core processing. The total processing time summed over all host machines was 41216 hours (4.7 years), justifying the need for a distributed computing approach.

Table 2. All decics unramified outside $S = \{2, 3\}$ and having a quadratic subfield, $\mathbb{Q}(\sqrt{d})$ with $d \in \{-1, \pm2, \pm3, \pm6\}$.

Acknowledgements

We would like to thank all the volunteers who donated the idle time on their cpus, especially Greg Tucker and Bill Brown, whose multi-core servers did more than 90% of the workload. Without these volunteers, the completion of the $\mathbb{Q}(\sqrt{6})$ case would not have been possible (at least for several years).
