# ANALYTIC CONTINUATION OF RIEMANN'S ZETA FUNCTION AND VALUES AT NEGATIVE INTEGERS VIA EULER'S TRANSFORMATION OF SERIES 

JONATHAN SONDOW

(Communicated by William W. Adams)

#### Abstract

We prove that a series derived using Euler's transformation provides the analytic continuation of $\zeta(s)$ for all complex $s \neq 1$. At negative integers the series becomes a finite sum whose value is given by an explicit formula for Bernoulli numbers.

## 1. Introduction

Euler computed the values of the zeta function at the negative integers using both Abel summation ( 75 years before Abel) and the Euler-Maclaurin sum formula. (Comparison of these values with those he found at the positive even integers led him to conjecture the functional equation 100 years before Riemann!) Euler also used a third method, his transformation of series or (E) summation (see $\S 2$ ), to calculate $\zeta(-n)$, but only for $n=0,1,2$, and 4. (See [1; 4, §1.5; 5, volume 14, pp. 442-443, 594-595; volume 15, pp. 70-90; 7; 9, $\S \S 1.3,1.6,2.2,2.3 ; 10 ; 14$, Chapter III, $\S \S X V I I-X X]$.)

We observe in $\S 4$ that this last method in fact yields

$$
\zeta(-n)=(-1)^{n} B_{n+1} /(n+1) \text { for all } n \geq 0
$$

but we require an explicit formula for Bernoulli numbers that was discovered a century after Euler. In $\S 3$ we justify the method by proving that a series used in $\S 4$ gives the analytic continuation of $\zeta(s)$ for all $s \neq 1$. Similar results for approximations to Euler's transformation are obtained in §5, as well as an evaluation of $\zeta^{\prime}(0) / \zeta(0)=\log 2 \pi$.

In a paper in preparation, the author will apply the method to other zeta functions and to Dirichlet $L$-series.

## 2. Euler's transformation of series

Any convergent series of complex numbers, written with alternating signs as

$$
A=a_{1}-a_{2}+a_{3}-\cdots,
$$

[^0]can also be written in the form
$$
A=\frac{1}{2} a_{1}+\frac{1}{2}\left[\left(a_{1}-a_{2}\right)-\left(a_{2}-a_{3}\right)+\cdots\right] .
$$

Repeating the process on the series in brackets, we have

$$
A=\frac{1}{2} a_{1}+\frac{1}{4}\left(a_{1}-a_{2}\right)+\frac{1}{4}\left[\left(a_{1}-2 a_{2}+a_{3}\right)-\left(a_{2}-2 a_{3}+a_{4}\right)+\cdots\right]
$$

and in general

$$
\begin{equation*}
\sum_{1}^{\infty}(-1)^{n-1} a_{n}=\sum_{0}^{k-1} \frac{\Delta^{j} a_{1}}{2^{j+1}}+\sum_{n=1}^{\infty}(-1)^{n-1} \frac{\Delta^{k} a_{n}}{2^{k}} \tag{1}
\end{equation*}
$$

where $\Delta^{0} a_{n}=a_{n}$ and

$$
\Delta^{k} a_{n}=\Delta^{k-1} a_{n}-\Delta^{k-1} a_{n+1}=\sum_{m=0}^{k}(-1)^{m}\binom{k}{m} a_{n+m}
$$

for $k \geq 1$. It is proved in [11, §33B] that the sum of the last series in (1) approaches 0 as $k \rightarrow \infty$, so that

$$
\begin{equation*}
\sum_{1}^{\infty}(-1)^{n-1} a_{n}=\sum_{0}^{\infty} \frac{\Delta^{j} a_{1}}{2^{j+1}} \tag{2}
\end{equation*}
$$

which is Euler's transformation of series. (See [5, volume 10, pp. 222-227; 9, $\S 4.6 ; 11, \S \S 35 \mathrm{~B}, 59,63]$. )

## 3. Analytic continuation of $\zeta(s)$

Instead of working directly with $\zeta(s)$, which for $\sigma=\operatorname{Re}(s)>1$ is given by $\zeta(s)=1^{-s}+2^{-s}+3^{-s}+\cdots$, let us consider the alternating series

$$
\begin{equation*}
\zeta(s)-2 \cdot 2^{-s} \zeta(s)=1^{-s}-2^{-s}+3^{-s}-\cdots \tag{3}
\end{equation*}
$$

which converges for $\sigma>0$ (see $\S 5$ ). Applying the Euler transformation, we have, for $\sigma>1$,

$$
\begin{align*}
\left(1-2^{1-s}\right) \zeta(s) & =\sum_{0}^{\infty} \frac{\Delta^{j} 1^{-s}}{2^{j+1}} \\
& =\sum_{0}^{\infty} \frac{1-\left(\begin{array}{l}
j \\
1 \\
1
\end{array}\right) 2^{-s}+\binom{j}{2} 3^{-s}-\cdots+(-1)^{j}\binom{j}{j}(j+1)^{-s}}{2^{j+1}} \tag{4}
\end{align*}
$$

Theorem. The analytic continuation of $\zeta(s)$ for all complex $s \neq 1$ is given by the product

$$
\begin{equation*}
\zeta(s)=\left(1-2^{1-s}\right)^{-1} \sum_{0}^{\infty} \frac{\Delta^{j} 1^{-s}}{2^{j+1}} \tag{5}
\end{equation*}
$$

in which the series converges absolutely and uniformly on compact sets to an entire function.
Proof. Fix $k \geq 0$. Evidently

$$
\Delta^{k} n^{-s}=(s)_{k} \int_{0}^{1} \cdots \int_{0}^{1}\left(n+x_{1}+\cdots+x_{k}\right)^{-s-k} d x_{1} \cdots d x_{k}
$$

for $k=1,2, \ldots$, where $(s)_{k}$ denotes the product $s(s+1) \cdots(s+k-1)$. Hence,

$$
\begin{equation*}
\left|\Delta^{k} n^{-s}\right| \leq\left|(s)_{k}\right| / n^{\sigma+k} \quad \text { whenever } \sigma+k \geq 0 \tag{6}
\end{equation*}
$$

$k=0,1,2, \ldots$, where $(s)_{0}=1$. Now let $S$ be a compact set in the half plane $\sigma>1-k$, and let $M_{n}$ denote the maximum of $\left|(s)_{k}\right| / n^{\sigma+k}$ on $S$. Then (6) implies that $\sum M_{n}$ dominates the series

$$
\begin{equation*}
\sum_{n=1}^{\infty}(-1)^{n-1} \Delta^{k} n^{-s} \tag{7}
\end{equation*}
$$

on $S$. It follows, using the triangle inequality, that the Euler transform of $\sum M_{n}$ dominates the Euler transform of (7), which, since $\Delta^{j} \Delta^{k}=\Delta^{j+k}$, is

$$
\sum_{j=0}^{\infty} \frac{\Delta^{j} \Delta^{k} 1^{-s}}{2^{j+1}}=\sum_{j=k}^{\infty} \frac{\Delta^{j} 1^{-s}}{2^{j+1-k}}
$$

Multiplying this by $1 / 2^{k}$ and adding $\sum_{0}^{k-1} \Delta^{j} 1^{-s} / 2^{j+1}$ produces the series in (4), which, since $k$ is arbitrary, therefore converges absolutely and uniformly on compact sets to an entire function. Since the series in (3) has zeros at the (simple) poles of $\left(1-2^{1-s}\right)^{-1}$ except at $s=1$ (for a direct proof see [12]), the theorem follows.

## 4. Evaluation of $\zeta(-m)$

Let $m$ be a positive integer or 0 . Note that $(-m)_{j}=0$ and, hence, $\Delta^{j} 1^{m}=$ 0 for $j>m$. Thus when $s=-m$ the series in (5) becomes a finite sum. Its value is given by a formula for Bernoulli numbers that Carlitz [2] attributes to Worpitzky [15] (see also [3]), namely, the second equality in the following.

Corollary. For $m=0,1,2, \ldots$,

$$
\zeta(-m)=\frac{1}{1-2^{m+1}} \sum_{0}^{m} \frac{\Delta^{j} 1^{m}}{2^{j+1}}=(-1)^{m} \frac{B_{m+1}}{m+1} .
$$

Alternatively, one can view $\zeta(-m)=(-1)^{m} B_{m+1} /(m+1)$ às known, which gives a proof of Worpitzky's formula (compare [6]).

## 5. Approximations to Euler's transformation

Note that (1), (3), and (6) imply (without using (2)) that for $k \geq 1$ the product

$$
\begin{equation*}
\zeta(s)=\left(1-2^{1-s}\right)^{-1}\left(\sum_{0}^{k-1} \frac{\Delta^{j} 1^{-s}}{2^{j+1}}+\frac{1}{2^{k}} \sum_{n=1}^{\infty}(-1)^{n-1} \Delta^{k} n^{-s}\right) \tag{8}
\end{equation*}
$$

provides the analytic continuation of $\zeta(s)$ on the punctured half plane $\sigma>1-k$, $s \neq 1$ where the infinite series converges absolutely and uniformly on compact sets to a holomorphic function. Moreover, except that the convergence will not be absolute in the strip $-k<\sigma \leq 1-k$, this remains true for $k \geq 0$ and $\sigma>-k$,
$s \neq 1$. (Proof. Grouping terms in pairs in the even partial sums of the second summation, we have

$$
\begin{aligned}
\sum_{n=1}^{2 N}(-1)^{n-1} \Delta^{k} n^{-s} & =\sum_{n=1}^{N}\left(\Delta^{k}(2 n-1)^{-s}-\Delta^{k}(2 n)^{-s}\right) \\
& =\sum_{n=1}^{N} \Delta^{k+1}(2 n-1)^{-s}
\end{aligned}
$$

Then it follows from (6) that both even and odd partial sums converge as required.) Since we can use (8) with $k \geq m+1$ to evaluate $\zeta(-m)$, the approximations (1) to Euler's transformation yield everything it does except formula (5).

As an example, take $k=1$ in (8):

$$
\zeta(s)=\left(1-\dot{2}^{1-s}\right)^{-1}\left(\frac{1}{2}+\frac{1}{2} \sum_{1}^{\infty}(-1)^{n-1}\left(n^{-s}-(n+1)^{-s}\right)\right)
$$

for $\sigma>-1, s \neq 1$. (This formula appears in Hardy's proof of the functional equation $[8 ; 13, \S 2.2]$ and gave the idea for the present note.) Thus $\zeta(0)=-1 / 2$ and, using Wallis's product for $\pi / 2$,

$$
\frac{\zeta^{\prime}(0)}{\zeta(0)}=2 \log 2+\log \frac{2}{1} \frac{2}{3} \frac{4}{3} \frac{4}{5} \cdots=\log 2 \pi
$$

which figures in the Hadamard product representation of the zeta function.
