EMBEDDING GENERAL ALGEBRAS INTO MODULES

MICHAŁ M. STRONKOWSKI AND DAVID STANOVKÝ

(Communicated by Birge Huisgen-Zimmermann)

ABSTRACT. The problem of embedding general algebras into modules is revisited. We provide a new method of embedding, based on Ježek’s embedding into semimodules. We obtain several interesting consequences: a simpler syntactic characterization of quasi-affine algebras, a proof that quasi-affine algebras without nullary operations are actually quasi-linear, and several facts regarding the “abelian iff quasi-affine” problem.

1. Introduction

Embedding one class of structures into a better understood one may widen a knowledge about the former class. We are interested in embedding (general) algebras into modules. Two similar types of representations appear in the literature:

- **Quasi-linear algebras** are subreducts of modules; their operations can be expressed as module terms, i.e. $r_1x_1 + \cdots + r_nx_n$.

- **Quasi-affine algebras** are subreducts of modules with additional nullary operations; their operations can be expressed as module polynomials, i.e. $r_1x_1 + \cdots + r_nx_n + c$ with a constant $c$.

Quasi-linear algebras are quasi-affine, and, somewhat surprisingly, one of our main results (Theorem 2.1) establishes the converse for all algebras without nullary basic operations (indeed, nullary operations are unlikely to have a linear representation).

Quasi-affine algebras were characterized syntactically by R.W. Quackenbush in [21]: obviously, in a fixed signature, quasi-affine algebras form a quasivariety, and Quackenbush found an infinite scheme of quasi-identities axiomatizing this class (for details, see [29]). His method for finding the conditions is based on the following two facts about affine algebras (i.e., polynomially equivalent to modules), discovered earlier by J.D.H. Smith and H.P. Gumm.

- An algebra is affine if and only if it is abelian and has a polynomial Mal’cev operation.

- A Mal’cev algebra is abelian if and only if the Mal’cev term is central.
(For all undefined notions, see Section 1.2.) Hence, Quackenbush’s task was to
determine under which conditions an algebra $A$ embeds into an algebra $B$
such that there is a Mal’cev central polynomial on $B$.

Here we follow a different path. We use J. Ježek’s embedding of algebras into
semimodules [11] and a folklore embedding of additively cancellative semimodules
into modules. We determine under which conditions the composition of the two em-
beddings yields a quasi-linear representation, and we obtain a set of quasi-identities,
which turn out to extend Quackenbush’s ones (see Theorem 2.1(3)). However,
quasi-affine algebras also satisfy our larger set. Hence every quasi-affine algebra
without nullary basic operations is quasi-linear. Our approach seems to have sev-
eral advantages over the Quackenbush approach: firstly, we obtain a linear (not
only affine) representation; secondly, our proof is shorter; and finally, despite the
fact that our axiomatizing scheme is larger, it has an easier-to-handle description.

Our result has some appeal to the “abelian iff quasi-affine” problem. Quasi-affine
algebras are always abelian, in the sense of commutator theory [3], meaning that
the diagonal is a block of a congruence of the square $A \times A$, or equivalently that
the quasi-identity

\[(TC) \quad t(x, u_1, \ldots, u_k) \approx t(x, v_1, \ldots, v_k) \rightarrow t(y, u_1, \ldots, u_k) \approx t(y, v_1, \ldots, v_k)\]

is satisfied for every term $t$. Modules and unary algebras are prototypical examples.

Not all abelian algebras are quasi-affine [21], although these two notions are
known to be equivalent under many additional assumptions (see Section 1.1). One
of the results of K.A. Kearnes [12] says that if an abelian algebra has a central
cancellative binary polynomial, then it is quasi-affine. We prove a stronger theorem.
It is sufficient to assume existence of a commutative cancellative binary polynomial
(Theorem 3.1 and Corollary 3.7). Every abelian algebra with a weak near-unanimity
polynomial is also shown to have such a polynomial (Corollary 3.8).

1.1. A little history. Linear and affine representations of algebras have a long
history. For instance, one of the basic results in quasigroup theory is the classical
Toyoda-Bruck-Murdoch theorem [1, 19, 30], saying that every medial (or entropic)
quasigroup is affine over a commutative ring. P. Němec and T. Kepka already
studied affine quasigroups over general rings in [20] under the name $T$-quasigroups
(nowadays, affine quasigroups are usually called central; see [25] for recent devel-
opments). In this context, Smith [24] was probably the first to realize the connec-
tion between affine representability and the abstract condition that is now called
abelianness.

However, things work in much greater generality. Smith [21], and independently
Gumm [15], showed that abelian Mal’cev algebras are affine (note that quasigroups
are Mal’cev algebras). This fact was used essentially to build a commutator theory
for congruence-permutable varieties in [24]. C. Herrmann in [19] extended this result
significantly: abelian algebras in congruence-modular varieties are affine. This fact
was used essentially to build a commutator theory for congruence-modular varieties
[3, 6, 17, 18]. Highlights of this theory include solutions of the RS and Park’s
conjectures for congruence-modular varieties [2, 16].

The “abelian iff affine” theorem can be pushed a bit further. Tame congruence
theory [10, Theorem 9.6(6)] yields that, if a locally finite variety $V$ satisfies a non-
trivial idempotent Mal’cev condition (i.e., if $V$ omits type 1), then abelian algebras
in $V$ are affine. For non-locally finite varieties, a stronger condition was proven to
be sufficient by Kearnes and Szendrei [14]: if \( \mathcal{V} \) satisfies an idempotent Mal'cev condition which fails in semilattices (in the locally finite case, it corresponds to omitting types 1, 5), then abelian algebras in \( \mathcal{V} \) are affine. The algebra \( (\mathbb{R}, \frac{x+y}{2}) \) shows that the assumption cannot be weakened to a non-trivial idempotent Mal'cev condition.

A weaker “abelian iff quasi-affine” theorem has been proved in several cases. For example, an abelian algebra \( \mathbf{A} \) is quasi-affine, if

1. \( \mathbf{A} \) is finite and simple (or more generally tame) (Hobby, McKenzie, Pálfy [10, Theorems 13.3 and 13.5]);
2. \( \mathbf{A} \) is simple idempotent (Kearnes [13, Theorem 3.8]);
3. \( \mathbf{A} \) has a central cancellative binary polynomial operation (Kearnes [12, Corollary 1.2]);
4. \( \eta_1 \cap \Delta = 0_{\mathbf{A}^2} \), where \( \eta_1 \) is the kernel of the first projection \( \mathbf{A}^2 \to \mathbf{A} \) and \( \Delta \) is the largest congruence on \( \mathbf{A}^2 \) admitting the diagonal as a block. Note that abelian algebras with a Taylor term satisfy this condition (Kearnes, Szendrei [14, Corollary 3.6]).

Regarding item (3), according to [27], we do not actually need to assume that \( \mathbf{A} \) is abelian; and in the present paper, we weaken the assumption of centrality to commutativity (see Theorem 3.1).

Finally, let us note that our interest in the topic originated in the theory of modes (idempotent entropic algebras). A.B. Romanowska and others were interested in embeddability of modes into modules. She and Smith [22, Chapter 7] proved that every cancellative mode is a subreduct of a module over a commutative ring. This fact was extended by the first author to entropic algebras in [26, 28]. The problem, whether all abelian modes have the property, remains unsettled.

Our historical exposition was partly based on the survey paper [29], where the reader can find more details about the methods and results.

1.2. Notation and terminology. The notation and terminology of universal algebra we use is rather standard and follows the book [17]. We quickly recall basic definitions.

An operation \( \sigma \) is called idempotent if the identity \( \sigma(x, x, \ldots, x) \approx x \) is valid.

A binary operation \( x \ast y \) is commutative if \( x \ast y \approx y \ast x \) is satisfied.

A ternary operation \( p \) is called Mal’cev if \( p(y, x, x) \approx p(x, x, y) \approx y \) hold. A Mal’cev algebra is an algebra possessing a Mal’cev term operation.

An \( n \)-ary operation \( w, \ n \geq 2, \) is called weak near-unanimity if it is idempotent and

\[
 w(y, x, \ldots, x) \approx w(x, y, x, \ldots, x) \approx \ldots \approx w(x, \ldots, x, y)
\]

are valid.

An \( n \)-ary operation \( (n \geq 2) \) is called Taylor if it is idempotent and for every \( i \leq n \) there are \( x_j, y_j, x \) \( \in \{x, y\}, \ j \neq i, \) such that the identity

\[
 t(x_1, \ldots, x_i, x, x_{i+1}, \ldots, x_n) \approx t(y_1, \ldots, y_i, y, y_{i+1}, \ldots, y_n)
\]

holds. For instance, a Mal’cev operation and a weak near-unanimity operation are Taylor. A binary operation is Taylor if it is idempotent and commutative.

An operation is called central if it commutes with all basic operations, i.e., if it is a homomorphism. Algebras where all basic operations are central are called entropic (or, in the case of groupoids, medial).
An operation \( \sigma \) is cancellative if the quasi-identity
\[
\sigma(x_1, \ldots, x_{i-1}, y, x_{i+1}, \ldots, x_n) \approx \sigma(x_1, \ldots, x_{i-1}, z, x_{i+1}, \ldots, x_n) \rightarrow y \approx z
\]
is satisfied for every \( i \leq n \).

A term is linear if each variable occurs in it at most once.

An algebra \( A \) is called a reduct of an algebra \( B \) if \( A = B \) and all basic operations of \( A \) are term operations of \( B \). It is called a subreduct if it is a subalgebra of a reduct of \( B \). (Sometimes we also say that \( A \) embeds into \( B \).)

A polynomial of an algebra \( A \) is an operation of the form \( p(x_1, \ldots, x_n) = t(x_1, \ldots, x_n, a_1, \ldots, a_m) \), where \( t \) is a term and \( (a_1, \ldots, a_m) \) is an \( m \)-tuple of elements of \( A \). Two algebras are polynomially equivalent if they have the same universes and the same sets of polynomial operations. Algebras polynomially equivalent to modules are called affine. Subreducts of affine algebras are called quasi-affine. Note that the definition of quasi-affineness given here is consistent with the one given at the beginning of the Introduction. Indeed, it follows from the fact that all polynomials of modules are of the form \( \sum_i x_i \) for some multiplicities \( x_i \).

By a semiring we mean a “unitary ring without subtraction”, which means an algebra \( R = (R, +, \cdot, 0, 1) \) such that both binary operations are associative, addition is commutative, multiplication distributes over addition, and the usual laws for 0, 1, i.e. \( 1r \approx r \approx r1 \) and \( 0r \approx r0 \approx r0 \) hold. A semimodule over a semiring \( R \), or an \( R \)-semimodule, is a “module without subtraction”, which means an algebra \( M = (M, +, 0, r : r \in R) \) such that \( (M, +, 0) \) is a commutative monoid, \( r \cdot \) are unary operations of multiplication by elements of \( R \) acting homomorphically on \( (M, +, 0) \), and the identities \( 1x \approx x \), \( 0x \approx 0 \), \( (r \cdot s)x \approx r(sx) \), \( (r + s)x \approx rx + sx \) are valid for all \( r, s \in R \). (All semimodules and modules in this article are supposed to be left.) A semimodule is additively cancellative if its addition is cancellative. It is a folklore fact that every additively cancellative semimodule is a subreduct of a module. For more information about semirings and semimodules, see [4, 8].

In the present paper, we will use the notion of a multiset in a slightly generalized setting: not only are elements allowed to have multiple presence, but also fractional. Formally, a multiset on \( X \) is a function from \( X \) into the semiring of non-negative rational numbers, usually denoted as a set of pairs \( (x, q) \), omitting the pairs with \( q = 0 \) and writing \( (x, 1) \) as \( x \). Note also that multisets on \( X \) may be identified with elements of the semimodule freely generated by \( X \) over the semiring of non-negative rational numbers. The multiset union will be denoted by \( \psi \).

2. QUASI-IDENTITIES FOR QUASI-LINEARITY

Let us fix a signature \( \Sigma \) without nullary basic operations. We will denote by \( \mathbb{N}(S) \) the semiring of polynomials over the natural numbers (including 0) with the set of non-commuting variables \( S = \{ \sigma_{(1)}, \ldots, \sigma_{(n)} \} \) with \( n \) and \( n \) is the arity of \( \sigma \). Note that \( \mathbb{N}(S) \) is a subreduct of the ring \( \mathbb{Z}(S) \) of polynomials over integers with the set of non-commuting variables \( S \).

Let \( \textbf{F}(X) \) be the free \( \mathbb{N}(S) \)-semimodule over a set \( X \). Every element of \( \textbf{F}(X) \) can be written (uniquely) as \( \sum_{x \in X} r_x x \) for some \( r_x \in \mathbb{N}(S) \), or equivalently, after redistributing polynomial terms, as \( \sum_{i=1}^n e_i x_i \) for some \( n, e_i \in S^* \) and \( x_i \in X \). Here \( S^* \) denotes the set of words with letters in \( S \). Terms of the latter sum will be called branches. The multiset of all branches of \( u \in \textbf{F}(X) \) will be denoted by
B(u). The complexity of \( \sum_{i=1}^{n} e_i x_i \), where \( e_i \in S^* \), \( x_i \in X \), is the length of the word \( e_1 \cdots e_n \).

In our considerations, \( \Sigma \)-terms over \( X \) will be identified with certain elements of \( F(X) \). Let \( F^\Sigma(X) \) be the \( \Sigma \)-reduct of \( F(X) \), where

\[
\sigma(u_1, \ldots, u_n) = \sigma(1) u_1 + \cdots + \sigma(n) u_n
\]

for every \( \sigma \in \Sigma \) of arity \( n \) and all \( u_1, \ldots, u_n \in F(X) \). Then the subalgebra \( T(X) \) of \( F^\Sigma(X) \) generated by \( X \) is absolutely free over \( X \). Thus we may identify a term with its evaluation in \( T(X) \) where each variable is assigned to itself. With this identification we may shortly and formally say what does it mean that a term \( s \) is a subterm of a term \( t \) at the address \( e \in S^* \), that is, \( t = u + e s \) for some \( u \). For an \((n+1)\)-tuple of terms \((t_0, \ldots, t_n)\) we will use the symbol \( B(t_0, \ldots, t_n) \) to denote \( B(t_0 + \cdots + t_n) \). The idea of the linear representation of terms is due to Ježek [11].

Example. Let \( \Sigma \) consist of a ternary operation \( \tau \), binary \( \beta \) and unary \( \alpha \). Then, e.g., the term \( t = \tau(\beta(x, y), \beta(z, x), \alpha(z)) \), with a parsing tree

\[
\begin{array}{c}
\tau \\
& \beta \\
& \beta \\
x & y & z \\
\end{array}
\]

is represented in \( F(\{x, y, z\}) \) as

\[
\tau(1) \beta(1)x + \tau(1) \beta(2)y + \tau(2) \beta(1)z + \tau(2) \beta(2)x + \tau(3) \alpha(1)z
\]

and the (multi)set of branches \( B(t) \) can be depicted as

\[
\begin{array}{c}
\tau(3) \tau(2) \tau(1) \\
\alpha(1) \beta(2) \beta(1) \beta(2) \beta(1) \\
z & x & y & x \\
\end{array}
\]

Example. Let \( \sigma \) be a ternary operation. Then we have

\[
B(\sigma(x, x, z), \sigma(y, y, z)) = B(\sigma(x, y, z), \sigma(y, x, z)).
\]

Theorem 2.1. For an algebra \( A \) without nullary basic operations, the following are equivalent:

1. \( A \) is quasi-affine (i.e., \( A \) is a subreduct of an affine algebra);
2. \( A \) is quasi-linear (i.e., \( A \) is a subreduct of a module);
3. \( A \) models the quasi-identity

\[
t_1 \approx s_1 \wedge \cdots \wedge t_m \approx s_m \rightarrow t_0 \approx s_0
\]

for each positive integer \( m \) and each pair of \((m+1)\)-tuples of terms satisfying \( B(t_0, \ldots, t_m) = B(s_0, \ldots, s_m) \).
As noted in the Introduction, the reasoning will be based on Ježek’s embedding of algebras into semimodules, though the proof is self-contained. Given an algebra $A$ over the signature $\Sigma$, we take the free $\mathbb{N}(S)$-semimodule $F(A)$ and generate a congruence $\theta$ by all pairs

$$(a, \sigma(1)a_1 + \cdots + \sigma(n)a_n)$$

such that $a, a_1, \ldots, a_n \in A$ and $a = \sigma(a_1, \ldots, a_n)$ in $A$. Then $a \mapsto a/\theta$ is an embedding of $A$ into the $\Sigma$-reduct of $F(A)/\theta$. For details, see [11] Section 3.

Let $\theta_+$ be the least congruence expansion of $\theta$ such that the semimodule $F(A)/\theta_+$ is additively cancellative. Then $F(A)/\theta_+$ is a subreduct of a $\mathbb{Z}(S)$-module, and we are left with the following question: does $A$ also embed into $F(A)/\theta_+$? That means, is $\theta_+|_A$ the identity relation?

**Lemma 2.2.** $u \theta_+ v$ iff there is $w \in F(A)$ such that $u + w \theta v + w$.

**Proof.** Note that $\theta_+$ has to contain all such pairs $(u, v)$. On the other hand, the binary relation thus defined is a congruence whose factor is additively cancellative. □

**Lemma 2.3.** $u \theta_+ v$ iff there are a natural number $m$ and $a_1, \ldots, a_m \in A$ such that $u + a_1 + \cdots + a_m \theta v + a_1 + \cdots + a_m$.

**Proof.** Note that for every $w \in F(A)$ there is $w' \in F(A)$ such that $w + w'$ is a sum of terms. Indeed, to each branch $u \in B(w)$ we associate a term $t_u \in T(A)$ containing $u$, and let $u'$ be such that $t_u = u + u'$. Then we may take $w' = \sum \{ w' \mid u \in B(w) \}$. However, for every $t \in T(A)$ there is $a \in A$ such that $t \theta a$. Now, use Lemma 2.2. □

Let us introduce some notation. For a term $t$ with variables in $A$, let $t^A$ be its evaluation in $A$, where each variable is assigned to itself. For $a \in A$ we will write $a \not\sim t$ if $a = ^A t$, and $\not\sim$ will be the converse relation. Observe that $^A t = ^A s$ iff $t (\not\sim \circ \not\sim) s$.

For $m$-tuples of terms, we will write $(a_1, \ldots, a_m) \not\sim (t_1, \ldots, t_m)$ if $a_i \not\sim t_i$ for all $i$.

We define a relation $\sim_m$, or simply $\sim$, on the set $T(X)^m$ by

$$(t_1, \ldots, t_m) \sim (s_1, \ldots, s_m)$$

iff $t_1 + \cdots + t_m = s_1 + \cdots + s_m$ in $F(X)$,

or in other words, iff the multisets of branches satisfy $B(t_1, \ldots, t_m) = B(s_1, \ldots, s_m)$.

For $a, b \in A$, let $a \rho^k_m b$ if there are $c_1, \ldots, c_m \in A$ such that $(a, c_1, \ldots, c_m) (\not\sim \circ \not\sim)^k (b, c_1, \ldots, c_m)$.

**Lemma 2.4.** For $a, b \in A$, $a \theta_+ b$ iff $a \rho^k_m b$ for some $k$ and $m$.

**Proof.** For $u, v \in F(A)$ let

(L) $u \lambda v$ if $u = w + e(\sigma(1)a_1 + \cdots + \sigma(n)a_n)$ and $v = w + ea$

for some $w \in F(A)$, $e \in S^*$, an $n$-ary operation $\sigma \in \Sigma$, and $a, a_1, \ldots, a_n \in A$ such that $\sigma(a_1, \ldots, a_n) = a$ in $A$. Then $\theta$ is the transitive and reflexive closure of $\lambda \cup \lambda^{-1}$, where $\lambda^{-1}$ is the inverse of $\lambda$.

**Claim.** Let $(u, v) \in \lambda \cup \lambda^{-1}$. If $u = t_0 + \cdots + t_m$, where all $t_i \in T(A)$, then there are $t_0', t_m' \in T(A)$ such that $(t_0, \ldots, t_m) \sim (t_0', \ldots, t_m')$, $v = t_0' + \cdots + t_m'$ and $(t_0', \ldots, t_m') (\not\sim \circ \not\sim)(t_0', \ldots, t_m')$.  

License or copyright restrictions may apply to redistribution; see https://www.ams.org/journal-terms-of-use
Proof of Claim. The statement in the case when \((u, v) \in \lambda^{-1}\) follows easily. Let \(v = w + e(\sigma(1) a_1 + \cdots + \sigma(n) a_n)\) and \(u = w + ea = t_0 + \cdots + t_m\). Let \(l \leq m\) be such that \(ea \in B(t_l)\). Put \(t'_l = t_l\) and let \(t''_l\) be the term obtained from \(t_l\) by substituting \(\sigma(a_1, \ldots, a_n)\) for \(a\) at the address \(e\) in \(t_l\); i.e. if \(t'_l = p + ea\), then \(t''_l = p + e(\sigma(1) a_1 + \cdots + \sigma(n) a_n)\). For \(k \neq l\) we may put \(t''_k = t'_k = t_k\).

Let us assume that \((u, v) \in \lambda\) and \(u, v\) are as in \((L)\). Let \(l_i \leq m\) be such that \(e(\sigma(i) a_i) \in B(t_{l_i})\). Then, in particular, \(t_{l_i}\) has a subterm \(\sigma(a_1, r_2, \ldots, r_n)\), where \(r_i \in T(A)\), at the address \(e\). Define \(t'_{l_i}\) as the term obtained from \(t_{l_i}\) by substituting \(a_i\) for \(r_i\) at the address \(e(\sigma(i))\) for all \(i \in \{2, \ldots, n\}\). Let \(t''_{l_i}, 2 \leq i \leq n,\) be the term obtained from \(t_{l_i}\) by substituting \(a_i\) for \(a_i\) at the address \(e(\sigma(i))\). (Note that it may happen that some \(a_i = r_i\), which means the respective changes are void.) Note that \(t_{l_i} + \cdots + t_{l_n} = t'_1 + \cdots + t'_{l_n}\). If \(k \neq l_i\) for all \(i\), let \(t''_k = t_k\). Then \(u = t'_0 + \cdots + t'_m\).

Now let \(t''_{l_i}\) be the term obtained from \(t'_{l_i}\) by substituting \(a\) for \(\sigma(a_1, \ldots, a_n)\) at the address \(e\), i.e. if \(t''_{l_i} = p + e(\sigma(1) a_1 + \cdots + \sigma(n) a_n)\), then \(t''_{l_i} = p + ea\). For other \(k \neq l_i\), let \(t''_k = t'_k\). Then \(v = t''_0 + \cdots + t''_m\), and since \(A t'_k = A t''_k\) for all \(k\), we obtain \(t'_0, t'_1, \ldots, t'_m \mapsto (\lambda \circ \rho)(t''_0, t''_1, \ldots, t''_m)\).

Assume \(a \theta+b\). By Lemma 2.3 there are \(c_1, \ldots, c_m \in A\) such that
\[ u := a + c_1 + \cdots + c_m \theta b + c_1 + \cdots + c_m = : v. \]

Thus there is a sequence \(u_0, \ldots, u_k \in T(A)\) such that \(u_0 = u, u_k = v\) and \((u_j, u_{j+1}) \in \lambda \cup \lambda^{-1}\) for all \(j\). By the Claim, there are terms \(t_{j,i}, t'_{j,i}, j = 0, \ldots, k, l = 0, \ldots, m,\) such that \(u_j = t_{j,0} + \cdots + t_{j,m} = t'_{j,0} + \cdots + t'_{j,m}\), and \(t_{j,i} \mapsto (\lambda \circ \rho) t_{j+1,i}\).

The converse implication in the statement is evident.

Lemma 2.5. For \(a, b \in A\), if \(a \rho^m b\), then \(a \rho^m b\) for some \(m'\).

Proof. Let
\[ (a_0, c_0) \mapsto (a_1, c_1) \mapsto (a_2, c_2) \mapsto \cdots \mapsto (a_k, c_k), \]
where \(a_0 = a, a_k = b, c_0 = c_k\). Then
\[ (a_0, c_0, a_1, c_1, \ldots, a_{k-1}, c_{k-1}) \mapsto (a_1, c_1, \ldots, c_k) \mapsto (a_k, c_k, a_1, c_1, \ldots, a_{k-1}, c_{k-1}). \]

(We get \(m' = (m + 1)k - 1\)).

Proof of Theorem 2.1 (3) \(\Rightarrow\) (2). Let \(a, b \in A\) and assume that \(a \theta b\). It follows from Lemmas 2.4 and 2.5 that there are \(c_1, \ldots, c_m \in A\) and terms \(t_0, \ldots, t_m, s_0, \ldots, s_m\) such that
\[ (a, c_1, \ldots, c_m) \mapsto (t_0, \ldots, t_m) \mapsto (s_0, \ldots, s_m) \mapsto (b, c_1, \ldots, c_m). \]

By assumption, \(A\) satisfies the quasi-identity
\[ t_1 \approx s_1 \wedge \cdots \wedge t_m \approx s_m \Rightarrow t_0 \approx s_0. \]

Note that in this quasi-identity, variables are elements of \(A\), and since
\[ A t_i = c_i = A s_i \]
for every \(1 \leq i \leq m,\)
\[ a = A t_0 = A s_0 = b. \]

Hence \(a \mapsto a / \theta\) is an embedding of \(A\) into a reduct of the additively cancellative semimodule \(F(A) / \theta\), and thus \(A\) is quasi-linear.
In order to prove the remaining implication, we start with some auxiliary definitions. First, to capture the affine representation of operations, let us introduce new symbols $c_\sigma$ for each $\sigma \in \Sigma$, and put $C_\Sigma = \{c_\sigma \mid \sigma \in \Sigma\}$. Let $G(X)$ be the $\mathbb{N}(S)$-semimodule $F(X \cup C_\Sigma)$ extended by $C_\Sigma$ as the set of nullary basic operations. Let $G^\Sigma(X)$ be the $\Sigma$-reduct of $G(X)$, where

\[(AFF) \quad \sigma(u_1, \ldots, u_n) = \sigma(1)u_1 + \cdots + \sigma(n)u_n + c_\sigma\]

for every $\sigma \in \Sigma$ with arity $n$ and all $u_1, \ldots, u_n \in G(X)$.

For a multiset of branches $B$ from $G(X)$ and $e \in S^*$, $\sigma \in \Sigma$, let $N_{e,\sigma}$ be the cardinality (counted with multiplicities) of the multiset

\[\{(e\sigma(x), q) \in B \mid 1 \leq i \leq \text{arity of } \sigma, \; x \in X \cup C_\Sigma\}\]

and let

\[B' = \left\{(e\sigma, \frac{N_{e,\sigma}}{\text{arity of } \sigma}) \mid e \in S^* \text{ and } \sigma \in \Sigma\right\}.

We set $B^* = B' \cup B'' \cup B''' \cup \cdots$.

**Example.** Let $\sigma, \tau$ be binary operations, $t_1 = \sigma(\tau(x, \sigma(x, y)), z)$, $t_2 = \sigma(x, z)$. Then one may compute

\[B(t_1, t_2) = \{\sigma(1)x, (\sigma(2)x, 2), \sigma(1)\tau(1)x, \sigma(1)\tau(2)x, \sigma(1)\tau(2)y, \sigma(1)\tau(2)\sigma(2)y\},
\]

\[B'(t_1, t_2) = \{(c_\sigma, 3/2), (\sigma(1)c_\tau, 1/2), \sigma(1)\tau(2)c_\sigma\},
\]

\[B''(t_1, t_2) = \{(c_\sigma, 1/4), (\sigma(1)c_\tau, 1/2)\},
\]

\[B'''(t_1, t_2) = \{(c_\sigma, 1/4)\},
\]

\[B^*(t_1, t_2) = \{(c_\sigma, 2), \sigma(1)c_\tau, \sigma(1)\tau(2)c_\sigma\}.
\]

In the above example all multiplicities in $B^*(t_1, t_2)$ are natural numbers. If $u$ is a sum of terms, then $B^*(u)$ always has natural multiplicities. This fact will be important in the following proof.

**Proof of Theorem 2.1** (1) \(\Rightarrow\) (3). First note that if a $\Sigma$-algebra is quasi-affine, then it is a subreduct of some $\mathbb{Z}(S)$-module $M$ extended by nullary operations corresponding to the symbols from $C_\Sigma$. Let $M^\Sigma$ be the $\Sigma$-reduct of $M$, where the basic operations are given by (AFF). Let $t_i, s_i$ be terms from $T(M)$ such that $B(t_0, \ldots, t_m) = B(s_0, \ldots, s_m)$. We just need to check that

\[(Q) \quad \text{if } M^S t_1 = M^S s_1, \ldots, M^S t_m = M^S s_m, \text{ then } M^S t_0 = M^S s_0.
\]

Let $\square: G(M) \to M$ be the $\mathbb{N}(S)$-semimodule homomorphism such that its restriction to $M$ is the identity mapping and $c_\sigma = c_\sigma$ for $\sigma \in \Sigma$.

**Claim.** For $t \in T(M)$ we have $M^S t = [t] + \sum B^*(t)$.

**Proof of Claim.** This follows inductively from the observation that

\[B^*(\sigma(t_1, \ldots, t_n)) = B^*(\sigma(1)t_1 + \cdots + \sigma(n)t_n) = \{c_\sigma\} \cup \bigcup_{i=1}^n \sigma(i)B^*(t_i). \quad \square\]
Because $B(t_0, \ldots, t_m) = B(s_0, \ldots, s_m)$, we have $B^*(t_0, \ldots, t_m) = B^*(s_0, \ldots, s_m)$, and by the Claim,

$$
M^E t_0 + \cdots + M^E t_m = (t_0 + \cdots + t_m) + \sum B^*(t_0, \ldots, t_m)
= s_0 + \cdots + s_m + \sum B^*(s_0, \ldots, s_m)
= M^E s_0 + \cdots + M^E s_m.
$$

This, together with the cancellativity of the addition in $M$, yields the satisfaction of (Q).

Let us note that the set of quasi-identities from condition (3) of Theorem 2.1 properly contains the original Quackenbush scheme. However, we found our description much easier to handle, in particular in view of the results in Section 3.

3. Application

**Theorem 3.1.** Let $A$ be an algebra without nullary basic operations and possessing a commutative cancellative polynomial $x \ast y$. Then $A$ is quasi-linear if and only if it is abelian.

In this section we will prove Theorem 3.1 and derive some consequences.

**Lemma 3.2.** An abelian commutative groupoid $A = (A, \ast)$ is entropic.

**Proof.** By commutativity we have the validity of $(x \ast y) \ast (z \ast x) \approx (x \ast z) \ast (y \ast x)$, and by (TC) the validity of $(x \ast y) \ast (z \ast t) \approx (x \ast z) \ast (y \ast t)$.

An operation $q(x_0, \ldots, x_m)$ is commutative if $q(x_0, \ldots, x_m) \approx q(x_{\pi(0)}, \ldots, x_{\pi(m)})$ is satisfied for every permutation $\pi$ of $\{0, \ldots, m\}$.

**Lemma 3.3.** An abelian algebra $A$ possessing a commutative cancellative binary polynomial $x \ast y$ has a commutative cancellative polynomial $q(x_0, \ldots, x_m)$ for arbitrary $m$.

**Proof.** For the sake of simplicity, we may assume that the operation $x \ast y$ is basic, i.e. $\ast \in \Sigma$. Let $l$ be a natural number. Let $t_l(x_0, \ldots, x_{2^l-1})$ be a linear $\{\ast\}$-term, where the addresses of all variables have length $l$. The cancellativity of $t_l$ is evident. We will prove inductively the commutativity of $t_l$. Term $t_0$ equals $x_0$, and the statement for it is trivial. For $t_l(x_0, x_1) = x_0 \ast x_1$ the assertion is just a part of the assumption of the lemma. So let $t_l = (t_{00} \ast t_{01}) \ast (t_{10} \ast t_{11})$, and assume that all $t_k$, $k < l$, are commutative. Assume that $x_0$ is the leftmost variable occurring in $t_l$. It is enough to prove that

$$
t_l(x_0, \ldots, x_{i-1}, x_i, x_{i+1}, \ldots, x_{2^l-1}) \approx t_l(x_i, \ldots, x_{i-1}, x_0, x_{i+1}, \ldots, x_{2^l-1})
$$

holds for every $i \in \{1, \ldots, 2^l - 1\}$. If $x_i$ occurs in $t_{00} \ast t_{01}$, then the assertion follows from the commutativity of this term. If $x_i$ occurs in $t_{10}$, then the assertion follows from the validity of $(t_{00} \ast t_{01}) \ast (t_{10} \ast t_{11}) \approx (t_{00} \ast t_{10}) \ast (t_{01} \ast t_{11})$, proved in Lemma 3.2 and the commutativity of $t_{10} \ast t_{10}$. Finally, if $x_i$ occurs in $t_{11}$, then the assertion follows from the commutativity of $t_{10} \ast t_{11}$ and the latter case.

Now choose $l$ such that $m + 1 \leq 2^l$, and define

$$
q(x_0, \ldots, x_m) = t_l(x_0, \ldots, x_m, d, \ldots, d),
$$

where $d$ is an arbitrary element of $A$.\[\square\]
Lemma 3.4. Let \( t(x, y_1, \ldots, y_n) \) and \( s(x, z_1, \ldots, z_m) \) be linear terms having the same branch containing \( x \), i.e. \( x \) is at the same address in \( t \) and \( s \). Then an abelian algebra satisfies the quasi-identity
\[
t(x_1, y_1, \ldots, y_n) \equiv s(x_1, z_1, \ldots, z_m) \Rightarrow t(x_2, y_1, \ldots, y_n) \equiv s(x_2, z_1, \ldots, z_m).
\]

Lemma 3.5. Let \( A \) be an abelian algebra possessing a commutative polynomial \( q(x_0, \ldots, x_m) \). If \( B(t_0, \ldots, t_m) = B(s_0, \ldots, s_m) \), where \( s_i, t_i \in T(\{ y \}) \), then \( A \) satisfies
\[
q(t_0, \ldots, t_m) \approx q(s_0, \ldots, s_m).
\]

Proof. We proceed by induction on the complexity of \( t_0 + \cdots + t_m \). If all terms \( t_i \) equal \( y \), then also all \( s_i \) equal \( y \), and the assertion is trivially satisfied. Let us assume that the above trivial case does not hold. Let us also assume that the assertion is valid for each pair of \((m+1)\)-tuples of terms of a smaller complexity than that of \( t_0 + \cdots + t_m \). Observe that there are \( e \in S^* \), \( \sigma \in \Sigma \) and \( i, j \in \{1, \ldots, m\} \) such that \( \sigma(y, \ldots, y) \) is a subterm of \( t_i \) and \( s_j \) at the address \( e \). By the commutativity of \( q \) we may assume that \( i = j = 0 \). Let \( t_0' \) be the term obtained from \( t_0 \) by substituting \( y \) for \( \sigma(y, \ldots, y) \) at the address \( e \), and let \( s_0' \) be obtained from \( s_0 \) in the same way. Let \( t_1' = t_1 \) and \( s_l' = s_l \) for \( l \geq 1 \). We have \( B(t_0', \ldots, t_m') = B(s_0', \ldots, s_m') \), and by the inductive assumption,
\[
q(t_0', \ldots, t_m') \approx q(s_0', \ldots, s_m').
\]

Now the assertion follows from Lemma 3.4.

Lemma 3.6. Let \( A \) be an abelian algebra possessing a commutative polynomial \( q(x_0, \ldots, x_m) \). If \( B(t_0, \ldots, t_m) = B(s_0, \ldots, s_m) \), where \( s_i, t_i \in T(X) \), then \( A \) satisfies
\[
q(t_0, \ldots, t_m) \approx q(s_0, \ldots, s_m).
\]

Proof. Let \( y \) be a variable not belonging to \( X \). We will define the sequence of multisets of branches \( B_j \) with natural multiplicities and the sequences of terms \( t_{i,j}, s_{i,j} \in T(X \cup \{ y \}) \) satisfying
\[
B_j = \{ e \in B(t_{0,j}, \ldots, t_{m,j}) \mid e \in S^* \text{ and } x \in X - \{ y \} \}
\]
and
\[
B(t_{0,j}, \ldots, t_{m,j}) = B(s_{0,j}, \ldots, s_{m,j})
\]
in the following way. Let \( B_0 = B(t_0, \ldots, t_m), t_{i,0} = t_i \) and \( s_{i,0} = s_i \). Assume that \( B_j \) and \( t_{i,j}, s_{i,j} \) are already defined. If \( B_j \neq \emptyset \), then take an arbitrary branch \( e \in B_j \), where \( e \in S^* \), \( x \in X \). There exist \( l, k \) such that \( e \in B(t_{l,j}) \) and \( e \in B(s_{k,j}) \). Let \( B_{j+1} = B_j \setminus \{ e \} \) and let \( t_{l,j+1} \) be the term obtained from \( t_{l,j} \) by substituting \( y \) for \( x \) at the address \( e \) (in other words, by substituting the branch \( ey \) for \( ex \)), let \( s_{l,j+1} \) be obtained from \( s_{k,j} \) in the same way, and let \( t_{l',j+1} = t_{l',j}, s_{k',j+1} = s_{k',j} \) for \( l' \neq l \) and \( k' \neq k \). Finally, let \( J \) be such that \( B_J = \emptyset \). Then \( t_{l,j} = t_l(y, \ldots, y), s_{l,j} = s_l(y, \ldots, y) \), for \( l \leq m \), and, by Lemma 3.5, \( A \) satisfies
\[
q(t_{0,j}, \ldots, t_{m,j}) \approx q(s_{0,j}, \ldots, s_{m,j}).
\]

 Lemma 3.4 together with the commutativity of \( q \), yields the validity of
\[
q(t_{0,j}, \ldots, t_{m,j}) \approx q(s_{0,j}, \ldots, s_{m,j}) \Leftrightarrow q(t_{0,j+1}, \ldots, t_{m,j+1}) \approx q(s_{0,j+1}, \ldots, s_{m,j+1}),
\]
for all \( j \). Thus \( q(t_0, \ldots, t_m) \approx q(s_0, \ldots, s_m) \) holds in \( A \).

Proof of Theorem 3.1. Use Lemmas 3.3 and 3.6 together with Theorem 2.1.
Now we may easily derive a strengthening of Kearnes’ theorem mentioned in the Introduction.

**Corollary 3.7.** Let $A$ be an abelian algebra without nullary basic operations and possessing a cancellative polynomial $x \bullet y$ such that $(A, \bullet)$ is entropic. Then $A$ is quasi-linear.

**Proof.** Define a binary cancellative commutative polynomial as $x * y = (d \bullet x) \bullet (y \bullet d)$, where $d \in A$, and use Theorem 3.1. □

Our last contribution is a new proof that an abelian algebra having a weak near-unanimity polynomial is quasi-affine. It is a special case of Kearnes’ and Szendrei’s theorem mentioned in subsection 1.1. The importance of such an operation follows from the fact, proved by M. Maróti and R. McKenzie in [15], that possessing a weak near-unanimity term is equivalent to having a Taylor term for locally finite varieties.

**Corollary 3.8.** Let $A$ be an abelian algebra without nullary basic operations and having a weak near-unanimity polynomial $w(x_1, ..., x_n)$. Then $A$ is quasi-linear.

**Proof.** Let $x * y = w(x, y, d, \ldots, d)$, where $d$ is an arbitrary element of $A$. In order to use Theorem 3.1 we will show that $x * y$ is commutative and cancellative.

Because $w$ is a weak near-unanimity operation, for $a, b \in A$,

$$w(a, \ldots, a, b, a, a, \ldots, a) = w(a, \ldots, a, a, b, a, \ldots, a),$$

where $b$ appears on the $i$th position on the left side and on the $(i + 1)$th position on the right side, $i < n$. By (TC) we obtain the equality

(C) $$w(c_1, \ldots, c_{i-1}, b, a, c_{i+2}, \ldots, c_n) = w(c_1, \ldots, c_{i-1}, a, b, c_{i+2}, \ldots, c_n)$$

for every $c_j \in A$. For $i = 1$ and $c_j = d$ this yields $a * b = b * a$. Now assume that $a * c = b * c$. By (TC) and (C), this implies that

$$a = w(a, \ldots, a) = w(b, a, \ldots) = w(a, b, a, \ldots, a).$$

Applying again (TC) and (C),

$$a = w(b, a, \ldots, a) = w(b, b, a, \ldots, a) = w(a, b, a, \ldots, a).$$

We may proceed in this way, finally obtaining

$$a = w(a, b, \ldots, b) = w(b, b, \ldots, b) = b.$$ □

We do not know the answer to the following question posed by the referee.

**Problem.** For finite algebras with finite signature without nullary basic operations, is the property of being quasi-linear decidable?

Note however that abelianness is decidable, as we may check whether the diagonal is a block of a congruence of the square of a given finite algebra with finite signature. Thus, if an algebra $A$ satisfies any of the known conditions guaranteeing that abelian algebras are quasi-linear, then in fact we may decide whether it is quasi-linear. Note also that the properties in the conditions (1)-(4) in Subsection 1.1 and in Theorem 3.1 are decidable.
