

SUNFLOWERS: FROM SOIL TO OIL

ANUP RAO

ABSTRACT. A *sunflower* is a collection of sets whose pairwise intersections are identical. In this article, we shall go sunflower-picking. We find sunflowers in several seemingly unrelated fields, before turning to discuss recent progress on the famous sunflower conjecture of Erdős and Rado, made by Alweiss, Lovett, Wu, and Zhang, as well as a related resolution of the *threshold vs expectation threshold conjecture* of Kahn and Kalai discovered by Park and Pham. We give short proofs for both of these results.

1. SUNFLOWERS

FIGURE 1. A sunflower with four petals

The moral of Ramsey theory is that large systems can exhibit surprising structure. There are many examples of this kind, starting with the prototypical one: every graph on n vertices either contains a clique¹ on $(1/2) \cdot \log_2 n$ vertices or an independent set² on $(1/2) \cdot \log_2 n$ vertices. Roth's theorem [15] proves that every subset of $\{1, \dots, n\}$ of density $\Omega(1)$ must contain an arithmetic progression.³ The Hales–Jewett theorem [9] and the Ajtai–Szemerédi corner theorem [1] are other examples of this phenomenon.

¹Mutually adjacent vertices

²Mutually nonadjacent vertices

³Three numbers $a, a + d, a + 2d$

A *sunflower* with w petals is a collection of w sets whose pairwise intersections are identical. The common intersection is called the *core*. In 1960, Erdős and Rado [4] proved a Ramsey theoretic result concerning sunflowers: every large collection of sets must contain a sunflower. They gave a simple inductive argument showing that every collection of more than $k! \cdot (w - 1)^k$ sets of size at most k must contain a sunflower with w petals.⁴ There are examples with $\Omega(w)^k$ sets that have no sunflowers, and they conjectured that the correct bound is $O(w)^k$.

The seeds were planted, and the search for sunflowers and sunflower lemmas began in earnest.

We begin this article by taking a tour through various fields where sunflowers are essential. We shall see examples relevant to finding arithmetic progressions in sumsets, understanding models of computation such as monotone boolean circuits and data structures, and we ask fundamental questions about the threshold of a monotone function. In each of these arenas, we skip details and zoom in to focus on the role played by sunflowers.

In 2019, Alweiss, Lovett, Wu, and Zhang [2] made significant progress toward proving the sunflower conjecture. Subsequent refining by myself [13], Frankston, Kahn, Narayanan, and Park [7], and Bell, Chueluecha, and Warnke [3] led to the result that every collection of $O(w \log k)^k$ sets of size at most k must contain a sunflower with w petals. A few months later, some of these ideas were used by Park and Pham [11] to give a surprisingly simple and elegant resolution of the *threshold vs expectation threshold conjecture* of Kahn and Kalai [10]. In this article, we present a version of these arguments that give the easiest proofs yet. In fact, we give a single argument that simultaneously proves the sunflower bound and resolves the conjecture about thresholds.

2. ARITHMETIC PROGRESSIONS IN SUMSETS

In 1992, Erdős and Sárközy [5] used sunflowers to find arithmetic progressions in subset sums. Given a set $T \subseteq \{1, \dots, n\}$, let $\text{sum}(T)$ denote the quantity $\sum_{x \in T} x$. Then they proved:

Theorem 1 ([5]). *Given any set $S \subseteq \{1, \dots, n\}$ of size $|S| \gg \log^2 n$, there are subsets $T_1, \dots, T_{w+1} \subseteq S$, with $w \approx |S|/\log^2 n$, such that the sequence $\text{sum}(T_1), \dots, \text{sum}(T_{w+1})$ is an arithmetic progression.*

Much like the sunflower lemma, this is an example of finding structure in a large system. However, the structure we seek here is an arithmetic progression; what does this have to do with sunflowers? Erdős and Sárközy move between the two structures as follows. First, by counting the number of possible sums that can be obtained by subsets of S and estimating a binomial coefficient, they show that some $(w \log n)^{\log n}$ subsets of S of size $\log n$ must attain the same sum. By the sunflower lemma, and the choice of parameters, this collection of sets is guaranteed to contain a sunflower. The proof is completed by Claim 2, whose proof we leave as an exercise (Figure 2):

⁴Often the sunflower lemma is stated under the assumption that each set is of size *exactly* k rather than at most k . Here we use the more general form because many applications rely on this form, and all of the ideas for proving the lemmas carry through.

FIGURE 2. Four petals induces an arithmetic progression of length 5.

Claim 2. If $S_1, \dots, S_w \subseteq \{1, \dots, n\}$ is a sunflower with core C , $|S_1| = \dots = |S_w|$, and $\text{sum}(S_1) = \text{sum}(S_2) = \dots = \text{sum}(S_w)$, then

$$\text{sum}(C), \text{sum}(S_1), \text{sum}(S_1 \cup S_2), \dots, \text{sum}(S_1 \cup \dots \cup S_w)$$

is an arithmetic progression.

3. MONOTONE CIRCUIT LOWER BOUNDS

Sunflowers have had a huge impact in theoretical computer science. Perhaps the most well-known example is Razborov's proof from 1985 [14] that there are no small monotone circuits computing the *clique* function. Here, we give a cartoon description of this clever argument.

A boolean circuit computes with the help of *gates* implementing boolean logic. These logic gates can compute the OR, AND, or negation of their inputs. The inputs to the gates are either the outputs of other gates or input variables. The size of the circuit is the number of wires used, which is the same as the number of connections made between gates. A *monotone* circuit is a boolean circuit that does not have any gates computing negations. The circuit computes a function if there is a gate whose value is equal to the value of the function, for every choice of the input variables.

For a graph G on n vertices and a set S of vertices, define

$$\text{clique}_S(G) = \begin{cases} 1 & \text{if } G \text{ contains a clique on the vertices of } S, \\ 0 & \text{otherwise.} \end{cases}$$

The function of interest for us is

$$\text{clique}_k(G) = \bigvee_{S \subseteq \{1, \dots, n\}, |S|=k} \text{clique}_S(G),$$

which computes whether or not the graph contains a clique of size k . Razborov's argument leads to Theorem 3:

Theorem 3 ([14]). *For every $\epsilon > 0$ and n large enough, every monotone circuit computing $\text{clique}_{n^{1/3-\epsilon}}(G)$ must have size at least $2^{\Omega(n^{1/6-\epsilon})}$.*

Razborov proves that this function requires exponentially large monotone circuits, if $k \approx n^{1/3}$. Razborov's result is one of the few examples where we are able to prove lower bounds on reasonable models of computation—it is a gem of theoretical computer science.

At a high level, sunflowers are used critically to show that any circuit computing clique_k can be used to obtain a smaller circuit with the same ability. Each such step involves a tiny error. We obtain a good approximation to the original circuit

that is so simple that we can directly reason that it does not work. This proves that the original circuit does not work either.

Now, let us give a few more details. Let G be a graph on n vertices that contains a uniformly random clique of size k and no other edges. Let H be a uniformly random $(k-1)$ -partite graph. G always contains a clique of size k , while H never contains a clique of size k . A monotone circuit computing the clique function would have to output 1 on G and 0 on H . An input variable to the circuit is the indicator for the presence of an edge, which can be thought of as clique_S for some set S of size 2.

Let us discuss how to approximate the circuit by a simpler circuit. First, we claim that $\text{clique}_S \wedge \text{clique}_T$ can be safely replaced by $\text{clique}_{S \cup T}$. This is because by the choice of G ,

$$\text{clique}_S(G) \wedge \text{clique}_T(G) \leq \text{clique}_{S \cup T}(G),$$

and by the choice of H ,

$$\text{clique}_S(H) \wedge \text{clique}_T(H) \geq \text{clique}_{S \cup T}(H).$$

Thus, carrying out this approximation preserves the ability of the circuit to distinguish G from H , while reducing the size of the circuit.

Sunflowers play a key role in approximating OR gates, via Claim 4:

Claim 4. If S_1, \dots, S_w form a sunflower with core C and all sets S_i are of size at most \sqrt{k} , then

$$\text{clique}_{S_1}(G) \vee \dots \vee \text{clique}_{S_w}(G) \leq \text{clique}_C(G),$$

and with high probability over the choice of H ,

$$\text{clique}_{S_1}(H) \vee \dots \vee \text{clique}_{S_w}(H) \geq \text{clique}_C(H).$$

When the input is G , the claim is trivial. When the input is H , the approximation causes a problem if there is a clique on C in H , yet none of the petals constitute a clique. This is extremely unlikely to happen: given that the core is a clique, the events that the petals are also cliques are independent, and the choice of parameters ensures that each occurs with probability $\Omega(1)$. So, one can argue that one of the petals will be a clique with probability $1 - 2^{-\Omega(w)}$.

Thus, if t is large enough, any expression of the type

$$\text{clique}_{S_1} \vee \dots \vee \text{clique}_{S_t}$$

can be approximated by a smaller expression of the same type—use the sunflower lemma to find a sunflower among the sets and replace it by the core. Repeatedly applying these operations, one can show that any arbitrary small monotone circuit can be approximated by a circuit whose structure is so simple that it is trivial to verify that it cannot distinguish G from H .

4. LOWER BOUNDS FOR DATA STRUCTURES

Data structures are a fundamental concept in computer science. They are used to efficiently maintain an object so that the object can be quickly modified and queried. Our next example is a lower bound on the running time of data structures for the problem of maintaining a set and computing its minimum. From my recent work with Ramamoorthy [12], building on ideas from [6, 8], our work shows the following:

Theorem 5 ([12]). *Any nonadaptive data structure of word size $\log n$ that allows us to add or delete elements from a subset T of $\{1, \dots, n\}$ and compute the minimum element of the set must access $\Omega(\log n / \log \log n)$ locations for some operation.*

The result is independent of the algorithm used to implement the data structure and the particular encoding of the data (namely T) used; the argument only relies on the sets of locations that the data structure reads and writes to. A valid data structure for our purposes is one that encodes the set T as a vector $\text{enc}(T) \in \{1, \dots, n\}^m$. The data structure is associated with a family of subsets of the coordinates of the encoding $S_0, S_1, \dots, S_n \subseteq \{1, \dots, m\}$ and an algorithm for manipulating $\text{enc}(T)$. For each i , the algorithm is able change $\text{enc}(T)$ to either $\text{enc}(T \cup \{i\})$ or $\text{enc}(T - \{i\})$ by reading and writing to the coordinates of $\text{enc}(T)$ given by S_i . The algorithm can compute the minimum of T by reading the coordinates given by S_0 . Under just these assumptions, the argument proves that some set S_i must be of size $\Omega(\log n / \log \log n)$.

If all of the sets S_0, S_1, \dots, S_n are of size $\ll \frac{\log n}{\log \log n}$, the choice of parameters implies that there is a sunflower among the sets $S_0 \cup S_1, S_0 \cup S_2, \dots, S_0 \cup S_n$. Suppose the sunflower corresponds to $S_0 \cup S_1, \dots, S_0 \cup S_w$, with $w \approx (\log n)^{100}$ and core C . By construction, we must have $S_0 \subseteq C$. The key claim is the following:

Claim 6. If $S_0 \cup S_1, \dots, S_0 \cup S_w$ is a sunflower with core C , then every subset of $T \subseteq \{1, \dots, w\}$ has an encoding as a vector in $\{1, \dots, n\}^{|C|}$.

This claim combined with a straightforward counting argument implies that $|C| \geq \Omega(\frac{\log n}{\log \log n})$, proving that one of the sets S_i must be large. To prove the claim, for any set T , arrive at its encoding by deleting the elements of the set $\{1, \dots, w\} - T$ from the encoding of $\{1, \dots, w\}$. After this process, every coordinate of $S_i - C$ for $i \in T$ has the same value that it had after the elements of $\{1, \dots, w\}$ were inserted. The claimed encoding corresponds to the contents of the core at this point, which is a string in $\{1, \dots, n\}^{|C|}$. T can be recovered from the encoding by computing the minimum of T , then deleting the minimum, then computing the minimum and deleting it, and repeating these operations over and over until the entire set T has been recovered. The minimum can always be computed using the core, since $S_0 \subseteq C$. Because for $i \neq j$, $S_i \cap S_j \subseteq C$, one never needs to keep track of the contents of coordinates outside the core; the contents of the core are enough to simulate the entire process and determine T .

5. ESTIMATING THE THRESHOLD OF MONOTONE FUNCTIONS

Suppose we sample a random graph by including each edge independently with probability ϵ . How can we estimate the probability that the graph contains a perfect matching?

This is a special case of a more general question. Let $2^{[n]}$ denote the set of subsets of $\{1, \dots, n\}$, and let $f : 2^{[n]} \rightarrow \{0, 1\}$ be a *monotone* function, meaning that $X \subseteq Y$ implies that $f(Y) \geq f(X)$. Let $\mathbf{X} \in 2^{[n]}$ be sampled by including each $i \in \mathbf{X}$ independently with probability ϵ . Because f is monotone, $\mathbb{E}[f(\mathbf{X})]$ is increasing in ϵ . The *threshold* of f is the value of ϵ for which $\mathbb{E}[f(\mathbf{X})] = 1/2$. There are a couple of generic ways to bound $\mathbb{E}[f(\mathbf{X})]$, and these bounds induce other kinds of thresholds that capture something about the structure of f . These ideas were explored extensively by Kahn and Kalai [10], Talagrand [16], Frankston, Kahn, Narayanan, and Park [7], and Park and Pham [11].

Given a family of sets \mathcal{F} and a set X , define the *shadow* $\mathcal{F}_X = \{F \in \mathcal{F} : F \subseteq X\}$. It is easy to see that every monotone function f admits a minimal collection of sets \mathcal{F} such that $f(X) = 1$ for $X \in \mathcal{F}$. Moreover, if \mathcal{F} is the minimal family for f , then $f(X) = 1$ if and only if $|\mathcal{F}_X| \geq 1$. So, by the union bound,

$$(5.1) \quad \mathbb{E}[f(\mathbf{X})] \leq \sum_{Y \in \mathcal{F}} \mathbb{P}[Y \subseteq \mathbf{X}] = \mathbb{E}[|\mathcal{F}_X|].$$

More generally, for every monotone function g with $f \leq g$, meaning that $f(X) \leq g(X)$ for all X , we have the bound,

$$(5.2) \quad \mathbb{E}[f(\mathbf{X})] \leq \mathbb{E}[|\mathcal{G}_X|],$$

where here \mathcal{G} is the family of minimal sets of g .

The *expectation threshold* of f is the largest value of ϵ for which the right-hand side of (5.2) is equal to $1/2$ for some monotone g with $f \leq g$. By (5.2), the threshold is always at least the expectation threshold. When f computes whether or not a graph has a perfect matching, the threshold is $\approx \frac{\log n}{n}$, while the expectation threshold is $\approx \frac{1}{n}$. Kahn and Kalai conjectured that this is the worst possible ratio: the threshold is always at most $O(\log n)$ times larger than the expectation threshold.

In general, the above union bound can be quite far from tight. It is not tight when the events $Y \subseteq \mathbf{X}$ have intersections of significant measure. There is a more sophisticated way to get upper bounds on $\mathbb{E}[f(\mathbf{X})]$, as observed by Talagrand [16]—it can be thought of as a fractional variant of the union bound discussed above. Suppose there is a probability distribution \mathbf{Z} on $2^{[n]}$ and κ satisfying

$$f(U) \leq \kappa \cdot \mathbb{E}[1_{\mathbf{Z} \subseteq U} \cdot \epsilon^{-|\mathbf{Z}|}]$$

for all sets U . Then we obtain the upper bound,

$$(5.3) \quad \mathbb{E}[f(\mathbf{X})] \leq \kappa \cdot \mathbb{E}[1_{\mathbf{Z} \subseteq \mathbf{X}} \cdot \epsilon^{-|\mathbf{Z}|}] = \kappa,$$

since for any fixed Z , the probability that $Z \subseteq \mathbf{X}$ is exactly $\epsilon^{|Z|}$.

The *fractional-expectation threshold* is the largest value of ϵ for which there is a \mathbf{Z} satisfying the above condition with $\kappa = 1/2$. The union bound of (5.2) can also be proved using (5.3), because if $f \leq g$ and \mathcal{G} is the set of minimal sets of g , then we can sample \mathbf{Z} so that

$$\mathbb{P}[\mathbf{Z} = Z] = \begin{cases} \frac{\mathbb{E}[1_{Z \subseteq \mathbf{X}}]}{\mathbb{E}[|\mathcal{G}_X|]} & \text{if } Z \in \mathcal{G}, \\ 0 & \text{otherwise,} \end{cases}$$

then because $\mathbb{E}[1_{Z \subseteq \mathbf{X}}] = \epsilon^{|Z|}$, we have that for any U

$$f(U) \leq g(U) \leq |\mathcal{G}_U| \leq \mathbb{E}[|\mathcal{G}_X|] \cdot \mathbb{E}[1_{\mathbf{Z} \subseteq U} \cdot \epsilon^{-|\mathbf{Z}|}],$$

proving (5.2). So, the bound given by (5.3) is certainly at least as good as the bound given by (5.2). In particular, this implies that the threshold is at least as large as the fractional-expectation threshold, which in turn is at least the expectation threshold. But how far apart can these numbers be?

Talagrand conjectured that the fractional-expectation threshold is within a multiplicative factor of $O(\log n)$ from the threshold and within an $O(1)$ factor of the expectation threshold. Following recent progress on the sunflower lemma, Frankston, Kahn, Narayanan, and Park [7] proved that the fractional-expectation-threshold is

within $O(\log n)$ of the threshold, thus resolving Talagrand’s first conjecture. Subsequently, Park and Pham proved that the expectation threshold is within a $O(\log n)$ factor of the threshold, resolving Kahn and Kalai’s conjecture:

Theorem 7 ([11]). *For any monotone function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, the threshold is at most $O(\log n)$ times larger than the expectation threshold.*

This allows us to compute the threshold for many graph properties, such as perfect matchings, Hamiltonian circuits, and bounded degree spanning trees. The ideas used to prove new sunflower lemmas play a key role in these proofs.

Talagrand made an important observation that suggests a definition that is ultimately used to prove the improved sunflower lemma. Suppose that κ is the smallest number for which there is a \mathbf{Z} establishing (5.3). Then by von Neumann’s minimax theorem, there is a distribution on \mathbf{U} such that for every choice of Z ,

$$(5.4) \quad \mathbb{E}[f(\mathbf{U})] \geq \kappa \cdot \mathbb{E}[1_{Z \subseteq \mathbf{U}} \cdot \epsilon^{-|Z|}].$$

Without loss of generality, we may assume that \mathbf{U} is supported on the minimal sets of f , since we can always modify the distribution in this way and preserve the inequality. So, after making this change, we can rewrite (5.4) as

$$(5.5) \quad \epsilon^{|Z|}/\kappa \geq \mathbb{E}[1_{Z \subseteq \mathbf{U}}].$$

This shows that \mathbf{U} has a very interesting property: it is *spread*, in the sense that it is unlikely to contain any fixed set Z : $\mathbb{P}[Z \subseteq \mathbf{U}] \leq \epsilon^{|Z|}/\kappa \leq r^{-|Z|}$ for $r = \kappa/\epsilon$.

The ideas used to prove the sunflower lemma are ultimately useful in proving the threshold vs expectation threshold conjecture, as well as the threshold vs fractional-expectation threshold conjecture. Let us briefly put on hold our study of these thresholds to discuss how the concept of being “spread” is useful in proving the new sunflower bound.

6. SUNFLOWERS IN SPREAD FAMILIES

At last we return to the sunflower question: how many sets of size k are sufficient to ensure the presence of a sunflower with w petals? Alweiss, Lovett, Wu, and Zhang discovered an elementary counting argument that is surprisingly powerful in helping answer this question.

Given a collection \mathcal{S} of sets, let $\mathbf{U} \in \mathcal{S}$ be uniformly random. As in Section 5, we shall say that \mathbf{U} is *r-spread* (for some parameter $r = O(w \log k)$) if for every set Z , $\mathbb{P}[Z \subseteq \mathbf{U}] \leq r^{-|Z|}$. Now, suppose $|\mathcal{S}| \geq r^k$. If \mathbf{U} is not *r-spread*, then there is a set Z such that the family $\mathcal{S}' = \{S \in \mathcal{S} : Z \subseteq S\}$ has at least $r^{k-|Z|}$ sets. In this case, we inductively find a sunflower in the family of sets of size at most $k - |Z|$ obtained by deleting Z from the sets of \mathcal{S}' . Adding Z back into this sunflower gives us a sunflower in our original family of sets. So, it only remains to find sunflowers in spread families.

We prove Claim 8 in Section 7. (All logarithms are computed base 2).

Claim 8. For $r = (64 \log k)/\epsilon$, if \mathcal{S} is such that \mathbf{U} is *r-spread* and \mathbf{W} is a uniformly random set of size ϵn , then $\mathbb{P}[\mathcal{S}_{\mathbf{W}} = \emptyset] \leq 1/2$.

Assuming the claim, let $\mathbf{W}_1, \dots, \mathbf{W}_{2w}$ be a random partition of the universe into $2w$ sets, and set $\epsilon = 1/(2w)$, so $r = 128w \log k$. Claim 8 implies that at least w of these sets will contain a set of the family in expectation, and so there must be w mutually disjoint sets—a sunflower with w petals.

7. A CLEVER COUNTING ARGUMENT

Finally, we arrive at the key technical theorem which will help us prove the new sunflower bound as well as resolve the threshold vs expectation threshold conjecture. Recall that we defined the shadow $\mathcal{G}_U = \{Y \in \mathcal{G} : Y \subseteq U\}$, and \mathbf{U} is r -spread if $\mathbb{P}[Z \subseteq U] \leq r^{-|Z|}$. We prove:

Theorem 9. *Let $\mathcal{S} \subseteq 2^{[n]}$ be a family of sets of size at most k . Then there is a distribution on pairs $(\mathbf{W}, \mathcal{G})$, where $\mathbf{W} \in 2^{[n]}$ is a uniformly random set of size ϵn and $\mathcal{G} \subseteq 2^{[n]}$ is a family of sets, such that either $\mathcal{S}_{\mathbf{W}} \neq \emptyset$ or for every $S \in \mathcal{S}$, $\mathcal{G}_S \neq \emptyset$ and yet for any r -spread \mathbf{U} that is independent of $(\mathbf{W}, \mathcal{G})$ with $r = (64 \log k)/\epsilon$, we have $\mathbb{E}[|\mathcal{G}_{\mathbf{U}}|] < 1/8$.*

Let us first use the theorem to complete our proofs of the sunflower lemma and the threshold vs expectation threshold conjecture.

7.1. Sunflower lemma. To prove Claim 8, let \mathcal{S} be the given family, and let \mathbf{U} be a uniformly random set of \mathcal{S} , which is r -spread with $r = (64 \log k)/\epsilon$. By the theorem, $\mathbb{E}[|\mathcal{G}_{\mathbf{U}}|] < 1/8$ implies that $\mathbb{P}[\forall S \in \mathcal{S}, \mathcal{G}_S \neq \emptyset] < 1/8$ and so $\mathbb{P}[\mathcal{S}_{\mathbf{W}} \neq \emptyset] > 7/8$, proving Claim 8.

7.2. Threshold vs expectation threshold. Let $\mathcal{S} = \mathcal{F}$ be the family of minimal sets of the given monotone function f and $k = n$. Let ϵ be the threshold of f , so $\mathbb{E}[f(\mathbf{X})] = 1/2$. Standard concentration bounds imply that there must be a number t with $|t - \epsilon n| < O(\sqrt{n})$ such that if \mathbf{W} is chosen to be a uniformly random set with $|\mathbf{W}| = t$, then $\mathbb{E}[f(\mathbf{W})] \leq 3/4$. For ease of presentation, let us assume that $t = \epsilon n$.

Let g denote the monotone function whose family of minimal sets is \mathcal{G} . By the theorem, either $f(\mathbf{W}) = 1$ or $f \leq g$, so

$$(7.1) \quad \mathbb{P}[f \leq g] \geq 1/4.$$

If \mathbf{U} is the distribution on sets where each element is included in \mathbf{U} independently with probability $1/r = \epsilon/(64 \log k)$, then \mathbf{U} is r -spread, so the theorem guarantees that $\mathbb{E}[|\mathcal{G}_{\mathbf{U}}|] < 1/8$. By Markov's inequality,

$$(7.2) \quad \mathbb{P}_{\mathcal{G}} \left[\mathbb{E}_{\mathbf{U}}[|\mathcal{G}_{\mathbf{U}}|] \geq 1/2 \right] < 1/4.$$

But (7.1) and (7.2) imply that there is a fixed choice of \mathcal{G} such that $f \leq g$ and $\mathbb{E}[|\mathcal{G}_{\mathbf{U}}|] \leq 1/2$, proving the threshold vs expectation threshold conjecture.

7.3. Proving Theorem 9. Let $\mathbf{W}_1, \mathbf{W}_2, \dots, \mathbf{W}_{\log k}$ be uniformly random disjoint sets of size $m = \epsilon n / \log k$. Here all logarithms are computed base 2. Our goal is to use $\mathbf{W}_1, \dots, \mathbf{W}_{\log k}$ to define sets $\mathcal{G}_1, \dots, \mathcal{G}_{\log k}$. We shall then set $\mathbf{W} = \mathbf{W}_1 \cup \dots \cup \mathbf{W}_{\log k}$ and $\mathcal{G} = \mathcal{G}_1 \cup \dots \cup \mathcal{G}_{\log k}$.

Let \mathbf{W}^i denote $\mathbf{W}_1 \cup \dots \cup \mathbf{W}_i$, and let \mathcal{G}^i denote $\mathcal{G}_1 \cup \dots \cup \mathcal{G}_i$. Define $\mathcal{G}_1, \dots, \mathcal{G}_{\log k}$ iteratively as follows. For each i and for $S \in \mathcal{S}$, include $S - \mathbf{W}^i$ in \mathcal{G}_i if and only if

- (i) $|S - \mathbf{W}^i| \geq k/2^i$, and
- (ii) $S - \mathbf{W}^i$ is a minimal set of $\{S - \mathbf{W}^i : S \in \mathcal{S}, \mathcal{G}_S^{i-1} = \emptyset\}$.

Intuitively, the above process attempts to *cover* all the sets of \mathcal{S} . In each step, we discard the elements of \mathcal{S} that have already been covered and proceed to cover more elements by including sets of size at least $k/2^i$ in \mathcal{G}_i . By the time $i = \log k$,

we will cover all remaining sets that are not included in $\mathbf{W}_1 \cup \dots \cup \mathbf{W}_{\log k}$. So, a set of \mathcal{S} is left uncovered in this process only if it is contained in $\mathbf{W} = \mathbf{W}^{\log k}$.

We give an upper bound on the expected number of sets $T \in \mathcal{G}_i$ of size a as follows. Fix $\mathbf{W}_1, \dots, \mathbf{W}_{i-1}$.

- (i) There are at most $\binom{n}{m+a}$ choices for the set $T \cup \mathbf{W}_i$ with $|T| = a$. We have

$$\binom{n}{m+a} = \binom{n}{m} \cdot \prod_{j=1}^a \frac{n-m-j}{m+j} \leq \binom{n}{m} \cdot \left(\frac{n}{m}\right)^a = \binom{n}{m} \cdot \left(\frac{\log k}{\epsilon}\right)^a.$$

- (ii) Given $T \cup \mathbf{W}_i$, let $S' - \mathbf{W}^{i-1}$ be the smallest set of $\{S - \mathbf{W}^{i-1} : S \in \mathcal{S}, \mathcal{G}_S^{i-1} = \emptyset\}$ that is contained in $T \cup \mathbf{W}_i$; break ties by picking the lexicographically first set. It must be that $|S' - \mathbf{W}^{i-1}| \leq k/2^{i-1}$, or else $S' - \mathbf{W}^{i-1}$ would have been included in \mathcal{G}_{i-1} . Furthermore, $T \subseteq S' - \mathbf{W}^{i-1}$, or $S' - \mathbf{W}^{i-1}$ would be a strict subset of T , and T would not be included in \mathcal{G}_i . So, there can be at most $2^{k/2^{i-1}} = 4^{k/2^i}$ choices for T consistent with $T \cup \mathbf{W}_i$.

The above count shows that the expected number of sets of size a in \mathcal{G}_i is at most $4^{k/2^i} \left(\frac{\log k}{\epsilon}\right)^a$. Thus, we can bound

$$\begin{aligned} \mathbb{E}[|\mathcal{G}_U|] &\leq \mathbb{E}\left[\sum_{Y \in \mathcal{G}} \left(\frac{\epsilon}{64 \log k}\right)^{|Y|}\right] \\ &= \sum_{i=1}^{\log k} \mathbb{E}\left[\sum_{Y \in \mathcal{G}_i} \left(\frac{\epsilon}{64 \log k}\right)^{|Y|}\right] \\ &\leq \sum_{i=1}^{\log k} \sum_{a=k/2^i}^{\infty} \left(\frac{\epsilon}{64 \log k}\right)^a \cdot 4^{k/2^i} \left(\frac{\log k}{\epsilon}\right)^a \\ &= \sum_{i=1}^{\log k} \frac{(1/16)^{k/2^i}}{1 - 1/64} \\ &< \sum_{j=1}^{\infty} 2 \cdot (1/16)^j < 1/8. \end{aligned}$$

This proves the theorem.

8. CONCLUSION

Sunflowers have had an enormous impact in a surprising number of different fields. They are certain to spring up in new places in the future. The counting method of [2] has already found applications in places where there are no sunflowers. It is an exciting time to be playing with these concepts!
