Roundoff Error Analysis of the Fast Fourier Transform

By George U. Ramos

Abstract. This paper presents an analysis of roundoff errors occurring in the floating-point computation of the fast Fourier transform. Upper bounds are derived for the ratios of the root-mean-square (RMS) and maximum roundoff errors in the output data to the RMS value of the output data for both single and multidimensional transformations. These bounds are compared experimentally with actual roundoff errors.

1. Introduction. The fast Fourier transform (FFT) is a very efficient algorithm for computing

\[ y(j) = \sum_{k=0}^{N-1} \exp(i2\pi jk/N)x(k) \quad (j = 0, 1, \ldots, N - 1), \]

where \( x(k) \) is a given set of complex numbers and \( i = \sqrt{-1} \). Let \( y' = (y(0), \ldots, y(N - 1)) \) and \( \text{fl}(y) \) be the floating-point representation of \( y \). In this paper, we derive bounds for

\[ \|\text{fl}(y) - y\|_{\text{RMS}}/\|y\|_{\text{RMS}} \quad \text{and} \quad \|\text{fl}(y) - y\|_{\infty}/\|y\|_{\text{RMS}}, \]

where

\[ \|z\|_{\text{RMS}} = \left( \frac{1}{N} \sum_k |z(k)|^2 \right)^{1/2} \quad \text{and} \quad \|z\|_{\infty} = \max_k |z(k)|. \]

These bounds include the effect of roundoff in computing sines and cosines and are obtained for both single and multidimensional transformations. Special consideration is given to cases when \( N \) is a multiple of 2 or 4.

The subject of roundoff error in the FFT has been studied and reported by others but with less generality or using a different approach. By comparing upper bounds, Gentleman and Sande [1] show that accumulated floating-point roundoff error is significantly less when one uses the FFT than when one computes (1.1) directly. In [2], Welch derives approximate upper and lower bounds on the RMS error in a fixed-point power-of-two algorithm. Weinstein [3] uses a statistical model for floating-point roundoff errors to predict the output-noise variance. Kaneko and Liu [4] also use a statistical approach and derive expressions for the mean-square error in a floating-point power-of-two transformation.

In the following sections, (1) the FFT algorithm is described in terms of a matrix factorization, (2) error bounds are derived, and (3) experimental comparisons of actual errors with error bounds are presented.

2. Matrix Factorization and the Fast Fourier Transform. In 1958, a matrix factorization for an algorithm similar to the FFT was described in a paper by I. J.
George U. Ramos

Good [15]. This paper led to the 1965 paper of Cooley and Tukey [5] in which the fast Fourier transform was introduced. Since then, many authors have presented matrix factorizations for the FFT. (See, for example, [6], [7], [8], [9], [13], and [14].)

Consider the complex Fourier transform of (1.1). This transform can alternatively be expressed as the matrix-vector equation

\[
\begin{align*}
\mathbf{y} &= T\mathbf{x}
\end{align*}
\]

where \( T \) is an \( N \)th-order matrix of complex exponentials

\[
T(j, k) = \exp(i2\pi jk/N) \quad (j, k = 0, 1, \cdots, N - 1).
\]

If this were to be computed directly, it would require \( N^2 \) complex multiplications and \( N(N - 1) \) complex additions. Instead, one can make use of the fact that

\[
T = P_{M+1}(B_M P_M)(D_{M-1}B_{M-1}P_{M-1}) \cdots (D_1B_1P_1),
\]

where \( P_l (l = 1, 2, \cdots, M + 1) \) are permutation matrices, \( D_l (l = 1, 2, \cdots, M - 1) \) are diagonal matrices of complex exponential elements (called rotation factors by Singleton [13], twiddle factors by Gentleman and Sande [1]), and \( B_l (l = 1, 2, \cdots, M) \) are block-diagonal matrices whose blocks on the diagonal are identical square submatrices, each the matrix of a complex Fourier transform of dimension \( N_l \). In this case, the required number of operations is reduced to \( N(M - 1 + \sum_{l=1}^M N_l) \) complex multiplications and \( N(2^M - 1) \) complex additions.

Description of the fast Fourier transform as a matrix factorization simplifies the following roundoff error analysis; but, before proceeding, a few remarks are in order. First, most factored-matrix formulations include only a single permutation matrix. The additional permutation matrices of (2.2) preserve diagonality. Second, the factors \( D_lB_l \) can be combined. The required multiplication count would then be \( N(\sum_{l=1}^M N_l) \). Third, the above operation counts do not take into account the fact that many of the complex exponentials are ±1 or ±√-1. And fourth, (2.2) holds for the Sande-Tukey algorithm as well as the Cooley-Tukey algorithm but with different diagonal matrices, \( D_l \) (see [1]).

3. Roundoff Errors in the Fast Fourier Transform. In this section, we first explain the roundoff error models used and then state and prove a theorem bounding the RMS and maximum errors.

We use models due to Wilkinson to mathematically represent the effect of roundoff in floating-point arithmetic operations. In [10] Wilkinson shows that the floating-point sum and floating-point product of two floating-point numbers \( a \) and \( b \) can always be expressed as

\[
\begin{align*}
\text{fl}(a + b) &= a(1 + \theta e) + b(1 + \theta e),
\end{align*}
\]

and

\[
\begin{align*}
\text{fl}(ab) &= ab(1 + \theta e),
\end{align*}
\]

where \( e \) is a computer-dependent constant and \( \theta \) is a generic variable usually different in value at each occurrence but always within the range \(-1 \) to \( 1 \). (The error constant, \( e \), is \( 0.5\beta^{1-\epsilon} \) for rounded operations or \( \beta^{1-\epsilon} \) for chopped operations, where \( \beta \) is the
number base of the floating-point computing system, \( t \) is the number of base-\( \beta \)
digits in the mantissa of the floating-point number, and at least \( t + 1 \) digits are used
to accumulate sums. For example, \( \epsilon = 16^{-8} \) in short-precision floating-point operations
on the IBM 360. If sums are accumulated with only \( t \) digits, \( \epsilon = 0.5(1 + 1/\beta)\beta^{1-t} \)
for rounded operations or \( (1 + 1/\beta)\beta^{1-t} \) for chopped operations.)

To represent roundoff in computing sines and cosines, we could model either
the relative error or the absolute error. If the arguments of the sines and cosines are
carefully computed, either model will result in approximately the same bound.
However, small errors in the arguments can result in large relative error when the
sine or cosine is very small. In this case, an absolute error model gives a better bound.
Hence we introduce an absolute error constant, \( \gamma \geq 0 \), such that

\[
\text{fl}(\sin(\text{fl}(a))) = \sin(a) + \gamma \theta \epsilon \quad \text{and} \quad \text{fl}(\cos(\text{fl}(a))) = \cos(a) + \gamma \theta \epsilon,
\]

where \( \theta \) and \( \epsilon \) are above. This constant depends on how sines and cosines and their
arguments are computed for a transformation of a given order, but it is independent
of the input data.

Let \( x' = (x(0), \cdots, x(N - 1)), y' = (y(0), \cdots, y(N - 1)) \) and \( \text{fl}(y) \) be the floating-point
representation of \( y \) and let

\[
||z||_{\text{RMS}} = \left( \sum_{k} |z(k)|^2 \right)^{1/2} \quad \text{and} \quad ||z||_{\infty} = \max_{k} |z(k)|.
\]

Then we have the following:

**Theorem 1.** If \( y = Tx \) is computed by a floating-point fast Fourier transform of
order \( N = N_1 N_2 \cdots N_M \), then

a. \( ||\text{fl}(y) - y||_{\text{RMS}}/||y||_{\text{RMS}} < K(N, \gamma) \epsilon + O(\epsilon^2) \) and

b. \( ||\text{fl}(y) - y||_{\infty}/||y||_{\text{RMS}} < \sqrt{N} K(N, \gamma) \epsilon + O(\epsilon^2), \)

where

\[
K(N, \gamma) = \sum_{i=1}^{M} \alpha(N_i) + (M - 1)(3 + 2\gamma)
\]

and

\[
\alpha(N_i) = \begin{cases} 
\sqrt{2} & \text{(if } N_i = 2), \\
5 & \text{(if } N_i = 4), \\
2\sqrt{N_i} (N_i + \gamma) & \text{otherwise}.
\end{cases}
\]

(In the case of radix-2 or radix-4 algorithms the important constants are

\[
K(2^M, \gamma) = (3 + \sqrt{2} + 2\gamma)M - (3 + 2\gamma), \quad \text{and}
\]

\[
K(4^M, \gamma) = (8 + 2\gamma)M - (3 + 2\gamma).
\]

These constants include the effect of separate multiplications by \( D_l \) (\( l = 1, 2, \cdots, M - 1 \)).

**Proof of a.** First consider computation of the inner product \( v = \sum_{l=1}^{n} a(l)u(l) \) by
the algorithm: begin \( v := a(1) \otimes u(1); \) for \( l := 2 \) step 1 until \( n \) do \( v := v + a(l) \otimes u(l) \)
end where it is known that \( u \) is exactly representable in floating point while \( a \) satisfies
\( \text{fl}(a(l)) = a(l) + \gamma \theta \epsilon \) for \( \gamma, \theta \) and \( \epsilon \) as above. By repeated application of (3.1) and (3.2), as in Wilkinson [10], one finds that

\[
\text{fl}(e) = (a(1) + \gamma \theta \epsilon)u(1)(1 + \theta \epsilon)^n + (a(2) + \gamma \theta \epsilon)u(2)(1 + \theta \epsilon)^{n-1} + \cdots + a(n)(1 + \gamma \theta \epsilon)u(n)(1 + \theta \epsilon)^2.
\]

Expanding factors \((1 + \theta \epsilon)^i\) and regrouping terms, this becomes

\[
\text{fl}(v) = v + \epsilon[(a(1)n\theta + \gamma \theta)u(1) + (a(2)n\theta + \gamma \theta)u(2) + (a(3)(n-1)\theta + \gamma \theta)u(3) + \cdots + (a(n)2\theta + \gamma \theta)u(n)] + O(\epsilon^2),
\]

where \(O(\epsilon^2)\) includes all terms of order \(\epsilon^2\). Thus, it follows that floating-point computation of the matrix vector product \(v = Au\), where \(\text{fl}(A(j, l)) = A(j, l) + \gamma \theta \epsilon\) and \(\text{fl}(u(l)) = u(l)\), is given exactly by

\[
(3.3)
\]

Next, consider computation of (1.1) without using the FFT. We write this complex computation as its real equivalent:

\[
\begin{bmatrix}
\text{fl}(v(1)) \\
\text{fl}(v(2)) \\
\vdots \\
\text{fl}(v(n))
\end{bmatrix} =
\begin{bmatrix}
v(1) \\
v(2) \\
\vdots \\
v(n)
\end{bmatrix}
+ \epsilon
\begin{bmatrix}
A(1, 1)n\theta + \gamma \theta & A(1, 2)n\theta + \gamma \theta & \cdots & A(1, n)2\theta + \gamma \theta & u(1) \\
A(2, 1)n\theta + \gamma \theta & A(2, 2)n\theta + \gamma \theta & \cdots & A(2, n)2\theta + \gamma \theta & u(2) \\
\vdots & \vdots & \ddots & \vdots & \vdots \\
A(n, 1)n\theta + \gamma \theta & A(n, 2)n\theta + \gamma \theta & \cdots & A(n, n)2\theta + \gamma \theta & u(n)
\end{bmatrix} +
O(\epsilon^2).
\]

where \(C\) and \(S\) are real matrices with elements \(C(j, k) = \cos (2\pi(j - 1)(k - 1)/N)\) and \(S(j, k) = \sin (2\pi(j - 1)(k - 1)/N)\) \((j, k = 1, 2, \cdots, N)\), and \(x_R, x_I, y_R, y_I\) are the real and imaginary parts of \(x\) and \(y\). Note that the RMS value of a complex vector is \(\sqrt{2}\) times as large as the RMS value of its real equivalent and that the RMS value of any vector is a multiple of the Euclidean norm and therefore is consistent with the same matrix norms as the Euclidean norm. [I.e., if \(v = Au\), then \(||v||_{\text{RMS}} \leq ||A|| \cdot ||u||_{\text{RMS}}\), where \(||A||\) is the Frobenius norm (the square root of the sum of the squared magnitudes of all elements) or the spectral norm (the square root of the largest eigenvalue of \(A^*A\)). See Wilkinson [10] or Isaacson and Keller [11].] Therefore, by (3.3) and the properties of norms,

\[
(3.4)
||\text{fl}(y) - y||_{\text{RMS}} \leq \epsilon \cdot ||M|| \cdot ||x||_{\text{RMS}} + O(\epsilon^2),
\]

where \(M\) is the matrix of Fig. 1. Using the fact that \(|C(j, k)|^2 + |S(j, k)|^2 = 1\), the
ROUNDOFF ERROR ANALYSIS OF FAST FOURIER TRANSFORM

\[
\begin{bmatrix}
C(1,1)\gamma^2 + \gamma & C(1,2)\gamma^2 + \gamma & \cdots & C(1,N)\gamma^2 + \gamma & -S(1,1)\gamma^2 + \gamma & \cdots & -S(1,N)\gamma^2 + \gamma \\
C(2,1)\gamma^2 + \gamma & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
\vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
C(N,1)\gamma^2 + \gamma & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
-S(1,1)\gamma^2 + \gamma & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
-S(2,1)\gamma^2 + \gamma & \vdots & \ddots & \vdots & \vdots & \cdots & \cdots \\
\vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
-S(N,1)\gamma^2 + \gamma & \cdots & \cdots & \cdots & \cdots & \cdots & C(N,N)\gamma^2 + \gamma
\end{bmatrix}
\]

**Figure 1. Direct Transformation Error Matrix**

Frobenius norm of \(M\) is bounded by

\[||M|| \leq \{N[(2N)^2 + (2N)^2 + (2N - 1)^2 + \cdots + 3^2 + 2^2]\}^{1/2} + 2N\gamma\]

when \(N\) is greater than 2.

Finally, we analyze the fast Fourier transform. Let \(z_1 = D_1B_1P_1x\). Since the permutation matrix simply reorders vector values, it introduces no roundoff error. Assume \(\text{fl}(x) = x\). Then

\[\text{fl}(z_1) - z_1 = \text{fl}(D_1\text{fl}(B_1P_1x)) - D_1B_1P_1x\]

\[= \text{fl}(D_1\text{fl}(v)) - D_1\text{fl}(v) + D_1[\text{fl}(B_1u) - B_1u],\]

where \(u = P_1x\) and \(v = B_1u\). To bound \(\text{fl}(B_1u) - B_1u\), recall that \(B_1\) is a block-diagonal matrix whose blocks are Fourier transform matrices of order \(N_1\). Let \(u_i, v_i (i = 1, 2, \cdots, N/N_1)\) be \(N_1\)-vectors such that

\[u = \begin{bmatrix}
u_1 \\
u_2 \\
\vdots \\
u_{N/N_1}
\end{bmatrix} \quad \text{and} \quad v = \begin{bmatrix}v_1 \\
v_2 \\
\vdots \\
v_{N/N_1}
\end{bmatrix}.
\]

Then by (3.4) and (3.5), \(||\text{fl}(v_i) - v_i||_{\text{RMS}} \leq C2N(N_1 + \gamma)||u_i||_{\text{RMS}} + O(\epsilon^2)\) \((i = 1, 2, \cdots, N/N_1)\) when \(N_1\) is greater than 2. If \(N_1 = 2\), this inequality still holds. In fact, we can do much better. Figs. 2 and 3 show the block-diagonal factor matrices.
for the cases when $N$ has factors 2 or 4. By inspection, one can see that in these cases no sines and cosines are computed, no multiplications are required, and there are only $N_i$ elements to be summed as compared with $2N_i - 1$ in other cases. Thus, one can easily show that

$$||f_l(v_i) - v_i||_{\text{RMS}} \leq \epsilon \sqrt{N_i} \alpha(N_i) ||u_i||_{\text{RMS}} + O(\epsilon^3) \quad (l = 1, 2, \ldots, N/N_i),$$

where

$$\alpha(N_i) = \begin{cases} 
\sqrt{2} & (N_i = 2), \\
5 & (N_i = 4), \\
2\sqrt{N_i} (N_i + \gamma) & \text{otherwise}.
\end{cases}$$

It immediately follows that
(3.7) \[ ||f_l(B_1u) - B_1u||_{\text{RMS}} \leq \epsilon \sqrt{N_1} \alpha(N_1) ||u||_{\text{RMS}} + O(\epsilon^2) \]

for \(\alpha(N_1)\) as above.

In the same way, we obtain a bound on the error in multiplication by the complex-diagonal matrix \(D_1\). The bound is given by

(3.8) \[ ||f_l(D_1f_l(v)) - D_1f_l(v)||_{\text{RMS}} \leq \epsilon(2\sqrt{2} + 2\gamma) ||f_l(v)||_{\text{RMS}} + O(\epsilon^2). \]

From (3.7) it follows that \(||f_l(v)||_{\text{RMS}} = ||v||_{\text{RMS}} + O(\epsilon)\). Furthermore, the spectral norms of \(D_1, B_1,\) and \(P_1\) are 1, \(\sqrt{N_1}\), and 1, respectively, since \(D_1^*D_1 = I, B_1^*B_1 = N_1I\) and \(P_1^*P_1 = I\), where \(I\) is the \(N\)-by-\(N\) identity matrix. So from (3.6), (3.7) and (3.8), we get

\[ ||f_l(z_1) - z_1||_{\text{RMS}} \leq \epsilon \sqrt{N_1} \left( \alpha(N_1) + 3 + 2\gamma \right)||x||_{\text{RMS}} + O(\epsilon^2), \]

where \(\alpha(N_1)\) is given above.

The next step is to let \(z_2 = D_2B_2P_2z_1\). Then

\[ f_l(z_2) - z_2 = f_l(D_2B_2P_2f_l(z_1)) - D_2B_2P_2f_l(z_1) + D_2B_2P_2[f_l(z_1) - z_1] \]

and

\[ ||f_l(z_2) - z_2||_{\text{RMS}} \leq \epsilon(N_1N_2)^{1/2} \left( \alpha(N_1) + \alpha(N_2) + 2(3 + 2\gamma) \right)||x||_{\text{RMS}} + O(\epsilon^2). \]

The proof of part a is completed by continuing in this manner and using (2.2).

Proof of b. The proof is extremely simple. Let \(e(j) = f_l(y(j)) - y(j)\). Then

\[ \max_i |e(j)|^2 \leq \sum_{j=0}^{N-1} |e(j)|^2, \]

from which it follows that

\[ \max_i |e(j)| \leq \sqrt{N} ||e||_{\text{RMS}}. \]

Substituting the bound of part a for \(||e||_{\text{RMS}}\) completes the proof.

It is not necessary to obtain a bound on the maximum error by using part a. Instead, one can use matrix infinity norms in the same fashion that matrix spectral norms were used above. But the infinity norms of the factor matrices, \(B_1\), are proportional to \(N_1\) rather than \(\sqrt{N_1}\), and so a higher bound results.

4. Roundoff Errors in Multidimensional Transformations. The efficiency of the fast Fourier transform has made it economically feasible to compute higher-dimensional Fourier transformations in applications such as picture processing and x-ray diffraction studies. In this section, bounds on roundoff errors in multidimensional FFT's are derived.

The problem is to bound roundoff errors in computing

\[ Y(t_1, t_2, \cdots, t_m) = \sum_{s_1} \sum_{s_2} \cdots \sum_{s_m} e(s_1t_1/N_1 + s_2t_2/N_2 + \cdots + s_mt_m/N_m) \]

(4.1)

\[ X(s_1, s_2, \cdots, s_m) \]

\((s_i, t_i = 0, 1, \cdots, N_i - 1; i = 1, 2, \cdots, m)\).
Let

\[ E(t_1, t_2, \ldots, t_m) = \text{fl}(Y(t_1, t_2, \ldots, t_m)) - Y(t_1, t_2, \ldots, t_m), \]

\[ \text{[fl}(Y) - Y]_{\text{RMS}} = \left\{ \left[ \sum_{i_1} \sum_{i_2} \cdots \sum_{i_m} |E(t_1, t_2, \ldots, t_m)|^2 \right] / N_1 N_2 \cdots N_m \right\}^{1/2}, \]

and

\[ \text{[fl}(Y) - Y]_{\text{MAX}} = \max_{t_1, t_2, \ldots, t_m} |E(t_1, t_2, \ldots, t_m)|. \]

Then we have

**Theorem 2.** The RMS and maximum error due to roundoff in a multidimensional fast Fourier transform are bounded by

a. \( \frac{[\text{fl}(Y) - Y]_{\text{RMS}}}{Y_{\text{RMS}}} \leq \varepsilon K(N_1, \gamma) + O(\varepsilon^2) \) and

b. \( \frac{[\text{fl}(Y) - Y]_{\text{MAX}}}{Y_{\text{RMS}}} \leq \varepsilon K(N_1, N_2 \cdots N_m)^{1/2} + O(\varepsilon^2) \), where \( K(N_1, \gamma) (l = 1, 2, \ldots, m) \) is the error constant given in Theorem 1.

**Proof.** Let (4.1) be rewritten as the system of equations

\[ Z_{l-1}(s_1, \ldots, s_{l-1}, t_l, \ldots, t_m) = \sum_{s_l} e(s_l t_l / N_l) Z_l(s_1, \ldots, s_l, t_{l+1}, \ldots, t_m) \quad (l = 1, 2, \ldots, m) \]

with \( Z_0 = Y \) and \( Z_m = X \), and describe this system of equations by the notation

\[ Z_{l-1} = T_l Z_l \quad (l = 1, 2, \ldots, m). \]

Then by adding and subtracting identical terms to the equation

\[ \text{fl}(Y) - Y = \text{fl}(T_1 \text{fl}(T_2 \cdots \text{fl}(T_m X) \cdots)) - T_1 T_2 \cdots T_m X, \]

one gets

\[ \text{fl}(Y) - Y = \text{fl}(T_1 \text{fl}(Z_1)) - T_1 \text{fl}(Z_1) \]

\[ + T_1 \text{fl}(T_2 \text{fl}(Z_2)) - T_1 T_2 \text{fl}(Z_2) \]

\[ + T_1 T_2 \text{fl}(T_3 \text{fl}(Z_3)) - T_1 T_2 T_3 \text{fl}(Z_3) \]

\[ + \cdots + T_1 T_2 \cdots T_{m-1} \text{fl}(T_m X) - T_1 T_2 \cdots T_m X. \]

Now take the RMS value of both sides and use the Cauchy-Schwarz inequality to get

\[ \text{[fl}(Y) - Y]_{\text{RMS}} \leq \left[ \text{fl}(T_1 \text{fl}(Z_1)) - T_1 \text{fl}(Z_1) \right]_{\text{RMS}} \]

\[ + [T_1 \text{fl}(T_2 \text{fl}(Z_2)) - T_1 T_2 \text{fl}(Z_2)]_{\text{RMS}} \]

\[ + \cdots + [T_1 T_2 \cdots T_{m-1} \text{fl}(T_m X) - T_1 T_2 \cdots T_m X]_{\text{RMS}}. \]

Using Theorem 1, it is not difficult to prove that

\[ \frac{[\text{fl}(Z_{l-1}) - Z_{l-1}]_{\text{RMS}}}{[Z_l]_{\text{RMS}}} \leq \varepsilon \sqrt{N_l} K(N_1, \gamma) + O(\varepsilon^2). \]

Nor is it difficult to prove

\[ [Z_{l-1}]_{\text{RMS}} = \sqrt{N_l} [Z_l]_{\text{RMS}}. \]

Therefore, by (4.2), (4.3) and (4.4),
\[ [f(Y) - Y]_{\text{RMS}} \leq \epsilon [(N_1)^{1/2} K(N_1, \gamma)[f(Z_1)]_{\text{RMS}} + (N_1N_2)^{1/2} K(N_2, \gamma)[f(Z_2)]_{\text{RMS}} + \cdots + (N_1N_2 \cdots N_m)^{1/2} K(N_m, \gamma)[f(X)]_{\text{RMS}}] + O(\epsilon^2). \]

But by (4.3), \[ [f(Z_l)]_{\text{RMS}} = [Z_l]_{\text{RMS}} + O(\epsilon) \quad (l = 1, 2, \cdots, m - 1), \]
and by (4.4), \[ [X]_{\text{RMS}} = (N_1^2 + N_2^2 \cdots N_m^2)^{1/2} [X]_{\text{RMS}}. \]
Assuming that \[ [f(X)]_{\text{RMS}} = [X]_{\text{RMS}}, \]
or at least \[ [f(X)]_{\text{RMS}} = [X]_{\text{RMS}} + O(\epsilon), \] the proof of part a is complete.

Part b is proved by arguments identical to those used in the proof of part b of Theorem 1.

5. Experimental Results. Roundoff error bounds are always pessimistic—sometimes so much so that they give no indication of the true error. To find out how pessimistic the error bounds of Section 3 are, the following experiment was performed. Using two different FORTRAN programs, one by N. M. Brenner [12] and the other by R. C. Singleton [13], a mixed radix fast Fourier transform of Gaussian data with mean 0 and variance 2 was computed in both short and long precision on the Stanford IBM 360/67. The actual error was computed as the difference between the short precision results and the truncated long precision results. The constant \( \gamma \)
used in determining the error bound, was computed by taking the difference between short precision and truncated long precision numbers representing sines and cosines.

The results of this experiment are given in Table 1. Note that the RMS error bound is roughly 20 times larger than the RMS error and the MAX error bound is roughly 2 orders of magnitude larger than the MAX error. Also note the relative size of the error bounds with respect to values of the transformed data. Even though the bounds are pessimistic, they might be used as a threshold for deciding what confidence to place in transformed data of relatively small magnitude.

6. Conclusion. In the preceding sections, roundoff errors in the floating-point fast Fourier transform have been analyzed. Bounds on RMS and maximum errors in transformed data were determined for both single and multidimensional transforms, and in the case of a one-dimensional transform results of a computational experiment show how close these bounds are to the actual roundoff errors. The bounds include the effect of roundoff in computing sines and cosines and, if contributions to the actual errors are in the same proportion as to the error bounds, a close look at the error bounds shows that the effect of roundoff in computing sines and cosines is not negligible but in fact contributes the same order of magnitude to the total error as the roundoff in additions and multiplications.

So far, nothing has been said about floating-point representation of input data. It was assumed that these numbers were exactly representable in machine precision. If not, an additional term must be added to the roundoff error to account for rounding input data. Suppose \( f(x) = x + \delta \). Then the additional term is

\[ ||T\delta||_{\text{RMS}} \leq \sqrt{N} ||\delta||_{\text{RMS}}. \]

On the other hand, suppose that the input data is known to a number of significant digits fewer than that of machine precision. For example, the data might have come from an analog device of limited accuracy. Then the bounds on roundoff error can

* Brenner's Program
** Singleton's Program
be used in reverse as suggested by the following: Let the roundoff error be given exactly by the complex $N$-vector $e$. This vector can be considered the exact solution of the equation $e = T\delta$ for some fictional $\delta$ bounded by

$$||\delta||_{RMS} = ||e||_{RMS}/\sqrt{N} \leq \epsilon K(N, \gamma) ||x||_{RMS} + O(\epsilon^2),$$

and

$$||\delta||_\infty \leq \epsilon \sqrt{N} K(N, \gamma) ||x||_{RMS} + O(\epsilon^2).$$

If it should turn out that $\epsilon \sqrt{N} K(N, \gamma) ||x||_{RMS}$ is smaller than the least significant digit of the input data, the roundoff error is negligible.

**Acknowledgments.** The author wishes to thank Professor Gene Golub of Stanford University for his advice and encouragement during the research for this paper. Special thanks also go to GTE Sylvania Incorporated for support received while the author was at Stanford. This research was done in partial fulfillment of the requirements for a doctoral degree in Computer Science.
