INDIFFERENTIABLE DETERMINISTIC HASHING TO ELLIPTIC AND HYPERELLIPTIC CURVES

REZA R. FARASHAHI, PIERRE-ALAIN FOUQUE, IGOR E. SHPARLINSKI, MEHDI TIBOUCHI, AND J. FELIPE VOLOCH

Abstract. At Crypto 2010, Brier et al. proposed the first construction of a hash function into ordinary elliptic curves that was indifferentiable from a random oracle, based on Icart’s deterministic encoding from Crypto 2009. Such a hash function can be plugged into essentially any cryptosystem that requires hashing into elliptic curves, while not compromising proofs of security in the random oracle model. However, the proof relied on relatively involved tools from algebraic geometry, and only applied to Icart’s deterministic encoding from Crypto 2009.

In this paper, we present a new, simpler technique based on bounds of character sums to prove the indifferentiability of similar hash function constructions based on any of the known deterministic encodings to elliptic curves or curves of higher genus, such as the algorithms by Shallue, van de Woestijne and Ulas, or the Icart-like encodings recently presented by Kammerer, Lercier and Renault. In particular, we get the first constructions of well-behaved hash functions to Jacobians of hyperelliptic curves.

Our technique also provides more precise estimates on the statistical behavior of those deterministic encodings and the hash function constructions based on them. Additionally, we can derive pseudorandomness results for partial bit patterns of such encodings.

1. Introduction

1.1. Hashing into elliptic curves. Many elliptic curve (especially pairing-based) cryptosystems require hashing into the group of points of an elliptic curve. For example, in the Boneh-Franklin IBE scheme [5], the public-key for identity \( id \in \{0, 1\}^* \) is a point \( Q_{id} = H_1(id) \) on the curve. This is also the case in many other pairing-based cryptosystems including IBE and HIBE schemes [1, 19, 20], signature and identity-based signature schemes [3, 6, 7, 11, 34] and identity-based signcryption schemes [9, 25].

Those cryptosystems are proved to be secure when the hash function is modeled as a random oracle into the curve, but it is not obvious how to instantiate this kind of hash function in such a way that the security proof can go through. As discussed by Brier et al. in [10], simple constructions that are easily distinguished from a random oracle are sufficient in some cases, owing to random self-reducibility properties of the underlying problems, but it is generally desirable to have proper hash functions that can be plugged into essentially any cryptosystem that requires
hashing into elliptic curves while not compromising proofs of security in the random oracle model.

The first example of such a hash function construction is due to Boneh and Franklin [5]. They use a particular supersingular elliptic curve $E$ endowed with a one-to-one mapping $f$ from the base field $\mathbb{F}_p$ to $E(\mathbb{F}_p)$, and define their hash function as $H(m) = f(h(m))$, where $h$ is a classical hash function from $\{0, 1\}^*$ to $\mathbb{F}_p$. They are able to prove that their IBE scheme remains secure when $h$ is seen as a random oracle into $\mathbb{F}_p$ (they don’t have to assume that $H$ itself is a random oracle into $E(\mathbb{F}_p)$).

In situations where shorter key sizes or asymmetric pairings are preferred, however, one wants to use ordinary elliptic curves, so the Boneh-Franklin construction does not apply. Two constructions for that case have been given by Brier et al. [10]. The main construction is valid for any ordinary elliptic curve $E$ over a field $\mathbb{F}_q$ such that $q \equiv 2 \pmod{3}$, and takes the form:

$$H(m) = f(h_1(m)) + f(h_2(m)),$$

where $h_1, h_2$ are regarded as independent random oracles with values in $\mathbb{F}_q$, and $f$ is Icart’s encoding into $E$, described in [21]. This construction is quite efficient, but the proof requires rather technical tools from algebraic geometry, and uses many particular properties of Icart’s function, which makes it difficult to adapt to other encodings or different settings. The alternate construction:

$$H(m) = f(h_1(m)) + h_2(m)G$$

with $G$ a generator of the group of points, can use a wider range of encoding functions $f$ instead of just Icart’s encoding, but is significantly less efficient (typically five times slower). Furthermore, the results of Brier et al. for these two constructions do not generalize in a natural way to hyperelliptic curves1.

1.2. Deterministic encodings. For hashing into an ordinary elliptic curve, the classical approach is in some sense probabilistic: one can prepend the message $m$ with a short, $\lceil \log_2 k \rceil$-bit long counter $c$ initialized to zero, and compute the hash value $x = h(c || m)$ for some $\mathbb{F}_q$-valued function $h$. If $x$ is the abscissa of a point on the elliptic curve $y^2 = x^3 + ax + b$, this gives the desired point; otherwise, one increments the counter and tries again. It is easy to see that step succeeds with probability about $1/2$ (for a random $m$), so if $k$ is the security parameter, $k$ steps are heuristically enough to construct a point except with negligible probability $\approx 2^{-k}$.

However, the length of the hash computation depends on the message $m$, which can lead to partition attacks [8, 12], unless all $k$ steps are run for all messages, and Legendre symbols and square roots are computed in constant time, in which case computational cost becomes prohibitive.

Therefore, it has been desirable to devise point construction algorithms on elliptic and hyperelliptic curves that are more robust.

The problem of generating points on ordinary elliptic curves over finite fields in deterministic polynomial time was first solved in a special case by Skalba [31], and a more general solution covering all isomorphism classes of elliptic curves was later given by Shallue and van de Woestijne [30]. Ulas subsequently proposed much

---

1Indeed, when applied to higher genus curves, the first method would involve overly cumbersome higher-dimensional algebraic geometry, and the second one would require encodings into the Jacobian variety with relatively large image, whereas constructions of encoding functions typically map to the curve itself.
simpler formulas based on similar ideas, and extended them to certain types of hyperelliptic curves in [32]. Icart’s paper at CRYPTO 2009 [21] sparked renewed interest in such algorithms, and several new ones have been presented recently [10, 23] both for elliptic and hyperelliptic curves. See §2.1 for a run-down of published encodings.

Techniques are known to establish a number of properties of these encodings, such as the size of their image into the curve [16, 18]. Those encodings which map into an elliptic curve can also be plugged into the second construction of Brier et al. mentioned in the previous section (and in the case of Icart’s encoding, into the first construction as well) to obtain well-behaved hash functions.

1.3. Our contributions. We introduce a new approach to deal with hash function constructions of the more general form:

\[ H(m) = f(h_1(m)) + \cdots + f(h_s(m)) \]

when \( f \) is any of the known deterministic encodings. We can show in particular that this construction is well-behaved (indifferentiable from a random oracle, in the random oracle model for the \( \mathbb{F}_q \)-valued functions \( h_i \)) as soon as \( s \) is greater than the genus of the target curve (that is, \( s \geq 2 \) for elliptic curves, \( s \geq 3 \) for genus 2 curves, etc.). We recover the results from Brier et al. [10] about Icart’s function as a special case with sharper bounds than in the original paper, and extend them to all known deterministic encodings, including new encodings to hyperelliptic curves.

For that purpose, we introduce the notion of well-distributed encoding, based on a new type of character sums associated with characters of the groups of points of the Jacobians of the target curves. We show that these sums can be estimated using classical results of Weil [33] and Bombieri [4], and combine these estimates with standard number-theoretic techniques in order to get explicit regularity results for functions of the form \( (u_1, \ldots, u_s) \mapsto f(u_1) + \cdots + f(u_s) \).

As a side contribution, we also investigate the pseudorandomness properties of sequences of bits extracted from these encoding functions. For example, while it is easy to distinguish the \( x \)-coordinate of a point constructed using Icart’s function from the \( x \)-coordinate of a random point on the same curve over \( \mathbb{F}_p \), it is not possible to construct a distinguisher when we are only given the top \((1/2 - \varepsilon) \log p\) bits of \( x \), where throughout this paper \( \log z \) means the base 2 logarithm of \( z \).

1.4. Organization of the paper. The paper is organized as follows:

- Section 2 is a summary of material from previous works, including a run-down of currently known deterministic encodings, and a review of relevant notions and results from Brier et al. [10];
- in Section 3, we introduce the notion of well-distributed encoding, and show how it can be used to derive regularity results formally (Theorem 1 and Theorem 3);
- Section 4 is more technical in nature and the details are not essential for applications: some machinery is introduced with the purpose of establishing Theorem 7, a convenient tool for proving well-distributedness;
in Section 5 we pick three illuminating examples of deterministic encodings to elliptic and hyperelliptic curves, prove that they are well-distributed, and deduce from our general results that they give rise to well-behaved hash functions. In particular, we give the first hash function constructions to Jacobians of curves of genus 2;

• finally, Section 6 is devoted to the separate problem of studying the uniformity of bit substrings from a deterministic encoding.

2. Previous Work

2.1. Deterministic encodings: a roundup. Table 1 lists known deterministic encodings to ordinary elliptic curves and hyperelliptic curves. They fit in two families:

• SWU-like encodings, similar to those proposed by Shallue, van de Woestijne and Ulas in [30, 32]. They are based on the construction of explicit rational curves on a surface associated to the target curve.

• Icart-like encodings, similar to Icart’s function [21]. They are obtained by writing down a root of the curve equation using radicals of degrees prime to the order of the multiplicative group. An alternate, elegant geometric interpretation of Icart-like encodings to elliptic curves (in terms of unicursal curves passing through the nine cusps of the dual curve) has recently been proposed by Couveignes and Kammerer [13].

The techniques presented in this paper make it possible to construct well-behaved hash functions from any of these encodings. We work out some examples in detail in §5.

As a side note, we can see that encoding functions are only known for relatively few families of hyperelliptic curves. On the other hand, all elliptic curves are covered by the construction of Shallue and van de Woestijne, although more efficient encodings with simpler formulas, such as Icart’s encoding and the simplified SWU encoding, are not known yet for Barreto-Naehrig curves [2], or more generally ordinary curves of \( j \)-invariant 0 and 1728.

2.2. Admissible encodings and indifferentiability. Brier et al. [10] use Maurer’s indifferentiability framework [27] to analyze the conditions under which their hash function constructions can be plugged into essentially any scheme\(^2\) that is proved secure in the random oracle model in such a way that the proof of security goes through. As shown by Maurer, it suffices that the hash function construction be indifferentiable from a random oracle.

Then, Brier et al. [10] establish a sufficient condition for a hash function construction into an elliptic curve \( E \) to be indifferentiable from a random oracle. It applies to hash functions of the form

\[
H(m) = F(h(m)),
\]

where \( F : S \to E(\mathbb{F}_q) \) is a deterministic encoding, and \( h \) is seen as a random oracle to \( S \). Assuming that \( h \) is a random oracle, the construction is indifferentiable whenever \( F \) is an admissible encoding into \( E(\mathbb{F}_q) \), in the following sense.

\(^2\)It has recently been pointed out by Ristenpart, Shacham and Shrimpton [28] that this type of composition result does not apply to literally all cryptographic protocols, but only those which admit so-called “single-stage security proofs”. This is not a significant restriction for the purpose at hand, as all protocols constructed so far using curve-valued hashing satisfy that requirement.
Table 1. Known deterministic encodings to ordinary elliptic curves and hyperelliptic curves. Some minor variants are omitted. Restrictions on the coefficients may apply.

A function $F : S \to R$ between finite sets is an $\varepsilon$-admissible encoding if it satisfies the following properties:

1. Computable: $F$ is computable in deterministic polynomial time.
2. Regular: for $s$ uniformly distributed in $S$, the distribution of $F(s)$ is $\varepsilon$-statistically indistinguishable from the uniform distribution in $R$.
3. Samplable: there is an efficient randomized algorithm $\mathcal{I}$ such that for any $r \in R$, $\mathcal{I}(r)$ induces a distribution that is $\varepsilon$-statistically indistinguishable from the uniform distribution in $F^{-1}(r)$.

A family of functions $F_k : S_k \to R_k$ indexed by a “security parameter” $k$ is said to be an admissible encoding if each $F_k$ is $\varepsilon(k)$-admissible, where $\varepsilon$ is a negligible function of $k$ (that is, $\varepsilon(k) = O(k^{-A})$ for any constant $A$).

This definition is motivated by the result of [10, Theorem 1] which asserts that if $F : S \to R$ is an admissible encoding, then the construction $H(m) = F(h(m))$ is indifferentiable from a random oracle, in the random oracle model for $h : \{0,1\}^* \to S$. 

A function $F : S \to R$ between finite sets is an $\varepsilon$-admissible encoding if it satisfies the following properties:
3. Well-distributed encodings

3.1. Character sums. Consider an encoding $f$ into a curve $X$, and let $J$ denote the Jacobian of $X$. Assume that $X$ has an $\mathbb{F}_q$-rational point $O$, so that we can fix an embedding $X \rightarrow J$ (sending a point $P$ to the degree 0 divisor $(P) - (O)$). Regularity properties of functions $f^\otimes s$ of the form

$$f^\otimes s : (\mathbb{F}_q)^s \rightarrow J(\mathbb{F}_q),$$

$$(u_1, \ldots, u_s) \mapsto f(u_1) + \cdots + f(u_s),$$

can be derived formally from the behavior of $f$ with respect to characters of $J(\mathbb{F}_q)$; see [22, 26] for a background on characters. More precisely, introduce the character sums

$$S_f(\chi) = \sum_{u \in \mathbb{F}_q} \chi(f(u)),$$

where $\chi$ is any character of the abelian group $J(\mathbb{F}_q)$. We say that $f$ is well-distributed if we have good bounds on the magnitude of $S_f(\chi)$ for nontrivial characters $\chi$.

**Definition 1.** Let $X$ be a smooth projective curve over a finite field $\mathbb{F}_q$, $J$ its Jacobian, $f$ a function $\mathbb{F}_q \rightarrow X(\mathbb{F}_q)$ and $B$ a positive constant. We say that $f$ is $B$-well-distributed if for any nontrivial character $\chi$ of $J(\mathbb{F}_q)$, the following holds:

$$|S_f(\chi)| \leq B\sqrt{q}.$$

Furthermore, we also consider well-distributed families of functions.

**Definition 2.** We say that a family of functions $f_k : \mathbb{F}_{q_k} \rightarrow X_k(\mathbb{F}_{q_k})$ as in Definition 1 is well-distributed if for some constant $B$ each of these functions is $B$-well-distributed.

As we show in §5, essentially all known deterministic encoding functions into elliptic and hyperelliptic curves satisfy (2) and we can thus establish results on the regularity of $f^\otimes s$ for any such encoding similar to those that Brier et al. [10] have obtained for $f^\otimes 2$ when $f$ is Icart’s function.

3.2. Collision probability. Besides character sums our estimates also depend on the number of solutions $W_f$ to the equation $f(u) = f(v)$ where $u, v \in \mathbb{F}_q$. We mention that it can be written as:

$$W_f = \sum_{D \in J(\mathbb{F}_q)} \left( \#f^{-1}(D) \right)^2.$$  

Indeed,

$$W_f = \sum_{f(u) = f(v)} 1 = \sum_{D \in J(\mathbb{F}_q)} \sum_{D \in J(\mathbb{F}_q)} \left( \sum_{u : f(u) = D} 1 \right)^2$$

as required. We also note that

$$\rho_f = W_f / q^2$$
is the probability of a collision. For all functions considered in this paper we have a bound of the type
\[
\rho_f \leq \frac{A_0}{q} + \frac{B_0}{q^2}
\]
with some explicit constants \( A_0 \) and \( B_0 \) (different for each function \( f \)).

3.3. Distribution of image sums. Fix a positive integer \( s \), and consider for any element \( D \in J(\mathbb{F}_q) \) the number of tuples \((u_1, \ldots, u_s)\) such that \( D = f(u_1) + \cdots + f(u_s)\):
\[
N_s(D) = \# \{(u_1, \ldots, u_s) \in (\mathbb{F}_q)^s \mid D = f(u_1) + \cdots + f(u_s)\}.
\]
We can establish the following result.

**Theorem 1.** If \( f : \mathbb{F}_q \rightarrow X(\mathbb{F}_q) \) is a \( B \)-well-distributed encoding into a curve \( X \), then for all \( D \in J(\mathbb{F}_q) \), we have:
\[
\left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \sum_{\chi} \chi(f(u_1) + \cdots + f(u_s) - D) \right| \leq \frac{B^{s-2}}{q^{s/2-1}} \left( \rho_f - \frac{1}{\#J(\mathbb{F}_q)} \right).
\]

**Proof.** Using the orthogonality relation
\[
\sum_{\chi} \chi(A) = \begin{cases} \#J(\mathbb{F}_q) & \text{if } A \text{ is the neutral element in } J(\mathbb{F}_q), \\ 0 & \text{otherwise}, \end{cases}
\]
where the summation is over all characters of \( J(\mathbb{F}_q) \), \( N_s(D) \) can be expressed in terms of character sums:
\[
N_s(D) = \sum_{u_1, \ldots, u_s \in \mathbb{F}_q} \frac{1}{\#J(\mathbb{F}_q)} \sum_{\chi} \chi(f(u_1) + \cdots + f(u_s) - D) \\
= \sum_{\chi} \frac{\chi(-D)}{\#J(\mathbb{F}_q)} \sum_{u_1, \ldots, u_s \in \mathbb{F}_q} \chi(f(u_1) + \cdots + f(u_s)) \\
= \sum_{\chi} \frac{\chi(-D)}{\#J(\mathbb{F}_q)} (S_f(\chi))^s.
\]
Putting aside the contribution of the trivial character \( \chi_0 \), we get:
\[
N_s(D) - \frac{q^s}{\#J(\mathbb{F}_q)} = \frac{1}{\#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} \chi(-D) (S_f(\chi))^s.
\]
Therefore, using [2], we derive
\[
\left| N_s(D) - \frac{q^s}{\#J(\mathbb{F}_q)} \right| \leq \frac{1}{\#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} |S_f(\chi)|^s \leq \frac{(B\sqrt{q})^{s-2}}{\#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} |S_f(\chi)|^2.
\]
On the other hand, \( W_f \), defined in Section 3.2 is just:
\[
W_f = \# \{(u_1, u_2) \in (\mathbb{F}_q)^2 \mid f(u_1) - f(u_2) = 0\} \\
= \sum_{u_1, u_2 \in \mathbb{F}_q} \frac{1}{\#J(\mathbb{F}_q)} \sum_{\chi} \chi(f(u_1) - f(u_s)) \\
= \frac{1}{\#J(\mathbb{F}_q)} \sum_{\chi} S_f(\chi)S_f(\overline{\chi})
and hence, putting aside the contribution of the trivial character as above and dividing by $q^2$, we get:

\[
\rho_f - \frac{1}{\#J(\mathbb{F}_q)} = \frac{1}{q^2 \#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} |S_f(\chi)|^2,
\]

from which the result follows immediately. \qed

**Corollary 2.** If $f : \mathbb{F}_q \rightarrow X(\mathbb{F}_q)$ is a $B$-well-distributed encoding into a curve $X$, then for all $D \in J(\mathbb{F}_q)$, we have:

\[
\left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right| < \frac{B^s}{q^{s/2}}.
\]

*Proof.* Plugging inequality (2) into (5), we see that:

\[
(6) \quad \rho_f - \frac{1}{\#J(\mathbb{F}_q)} \leq \frac{B^2}{q}.
\]

Together with Theorem 1, this concludes the proof. \qed

Suppose that $X$ is of genus $g_X$. Then $\#J(\mathbb{F}_q) = q^{g_X} + O(q^{g_X-1/2})$, so the bound of Corollary 2 is negligible compared to $1/\#J(\mathbb{F}_q)$ provided that $s > 2g_X$. In other words, if $f$ is a well-distributed encoding, then for $s > 2g_X$, all elements $D \in J(\mathbb{F}_q)$ have the same number of preimages by $f^{\otimes s}$ up to negligible deviation.

When $f$ is Icart’s function, this says that all the points of the target elliptic curve have almost the same number of preimages by $f^{\otimes s}$ for $s \geq 3$. This cannot be improved to $s = 2$, as the analysis in [10] shows that there is in fact a bounded number of points which have several times more preimages by $f^{\otimes 2}$ than the others.

Nevertheless, Brier et. al. [10] could obtain their indifferentiability result by bounding the statistical distance between the distribution defined by $f^{\otimes 2}$ and the uniform distribution. We can establish a general result of this type for well-distributed encodings.

**Theorem 3.** If $f : \mathbb{F}_q \rightarrow X(\mathbb{F}_q)$ is a $B$-well-distributed encoding into a curve $X$, then the statistical distance between the distribution defined by $f^{\otimes s}$ on $J(\mathbb{F}_q)$ and the uniform distribution is bounded as:

\[
\sum_{D \in J(\mathbb{F}_q)} \left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right|^2 \leq \frac{B^{s-1}}{q^{(s-1)/2}} \sqrt{\rho_f \#J(\mathbb{F}_q)} - 1.
\]

*Proof.* We can first write the sum of squared deviations. Let

\[
V_s = \sum_{D \in J(\mathbb{F}_q)} \left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right|^2,
\]

and recall from the proof of Theorem 1 that

\[
\frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} = \frac{1}{q^s \#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} \chi(-D) (S_f(\chi))^s.
\]
As a result, we can write $V_s$ as follows:

$$
V_s = \sum_{D \in J(\mathbb{F}_q)} \frac{1}{q^{2s} \#J(\mathbb{F}_q)^2} \left| \sum_{\chi \neq \chi_0} \chi(-D) (S_f(\chi))^s \right|^2
$$

$$
= \sum_{D \in J(\mathbb{F}_q)} \frac{1}{q^{2s} \#J(\mathbb{F}_q)^2} \sum_{\chi, \eta \neq \chi_0} \chi(-D) \eta(-D) (S_f(\chi) S_f(\eta))^s
$$

$$
= \frac{1}{q^{2s} \#J(\mathbb{F}_q)^2} \sum_{\chi \neq \chi_0} \left( \sum_{D \in J(\mathbb{F}_q)} \chi(D) \eta(D) \right) (S_f(\chi))^s
$$

$$
= \frac{1}{q^{2s} \#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} |S_f(\chi)|^{2s}
$$

since the sum $\sum_{D \in J(\mathbb{F}_q)} \chi(D) \eta(D)$ vanishes unless $\chi = \eta$. Using (2) and (5) successively, we derive:

$$
V_s \leq \frac{B^{2s-2}}{q^{s+1} \#J(\mathbb{F}_q)} \sum_{\chi \neq \chi_0} |S_f(\chi)|^2 \leq \frac{B^{2s-2}}{q^{s-1}} \left( \rho_f - \frac{1}{\#J(\mathbb{F}_q)} \right).
$$

On the other hand, the Cauchy-Schwarz inequality gives:

$$
\sum_{D \in J(\mathbb{F}_q)} \left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right| \leq \sqrt{\#J(\mathbb{F}_q)} V_s,
$$

which concludes the proof. 

**Corollary 4.** If $f : \mathbb{F}_q \to X(\mathbb{F}_q)$ is a $B$-well-distributed encoding into a curve $X$, then the statistical distance between the distribution defined by $f^{\otimes s}$ on $J(\mathbb{F}_q)$ and the uniform distribution is bounded as:

$$
\sum_{D \in J(\mathbb{F}_q)} \left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right| \leq \frac{B^s}{q^{s/2} \#J(\mathbb{F}_q)}.
$$

**Proof.** The proof is the same as for Corollary 2, just plug the bound on $\rho_f$ given by (3) into the statement of Theorem 3. 

In particular, we see from Corollary 3 that if $f$ is a well-distributed encoding, then for $s > g_X$, the distribution defined by $f^{\otimes s}$ on $J(\mathbb{F}_q)$ is statistically indistinguishable from the uniform distribution. If $f$ is also computable and samplable (which is easily verified to be the case when $f$ is any of the known deterministic encodings), then it is admissible. In particular, the hash function construction,

$$
m \mapsto f(h_1(m)) + \cdots + f(h_s(m)) \quad (s = g_X + 1),
$$

is indifferentiable from a random oracle if $h_1, \ldots, h_s$ are seen as independent random oracles into $\mathbb{F}_q$.

---

3 More formally, if for each positive integer $k$, $X_k$ is a curve over $\mathbb{F}_{q_k}$ with $q_k = 2^{\Omega(k)}$, and if $f_k : \mathbb{F}_{q_k} \to X_k(\mathbb{F}_{q_k})$ is a well-distributed function family such that the family $f_k^{\otimes s}$ is polynomially computable and samplable, then that latter family is admissible.
4. Character sums on curves

Throughout this section a “curve” means smooth, projective, geometrically connected curve over \( \mathbb{F}_q \). Let \( Y \to X \) be a morphism of curves which is an abelian covering with Galois group \( G \) (that is, a nonconstant morphism such that the corresponding extension of function fields \( \mathbb{F}_q(Y)/\mathbb{F}_q(X) \) is abelian with Galois group \( G \)).

Any character of \( G \) determines, via the Artin map, a corresponding character on the group of \( \mathbb{F}_q \)-divisors on \( X \) prime to the ramification locus \( S \) of \( Y \to X \), which extends to a multiplicative map \( \chi \): \( \text{Div}_{\mathbb{F}_q}(X) \to \mathbb{C} \) vanishing on divisors not prime to \( S \). Let us call such a map \( \chi \) an Artin character of \( X \). One associates to \( \chi \) a distinguished effective divisor \( f(\chi) \) of support \( S \) called the conductor (in particular, if \( Y \to X \) is unramified, \( f(\chi) = 0 \); the character itself is then said to be unramified).

**Example 5.** We consider the following examples of Artin characters.

- Let \( E \) be an elliptic curve over \( \mathbb{F}_q \). Then any character of the abelian group \( E(\mathbb{F}_q) \) extends to an unramified Artin character of \( E \). Indeed, if \( F \) denotes the Frobenius endomorphism of \( E \), \( 1 - F: E \to E \) is an unramified abelian covering with group \( G = E(\mathbb{F}_q) \), and characters of \( G \) determine Artin characters of \( E \) whose restriction to \( E(\mathbb{F}_q) \) is as expected.
- More generally, let \( X \) be any curve over \( \mathbb{F}_q \) with an \( \mathbb{F}_q \)-point, and \( J \) its Jacobian. As usual, we can embed \( X \) in \( J \) using this rational point. Then any character of the group \( J(\mathbb{F}_q) \) extends to an Artin character of \( X \). It is constructed similarly; \( 1 - F: J \to J \) is again an unramified abelian covering with group \( J(\mathbb{F}_q) \) which can be pulled back to an abelian covering \( Y \to X \) with group \( J(\mathbb{F}_q) \) along the embedding \( X \to J \).
- If \( \chi \) is an Artin character on \( X \), and \( h : \tilde{X} \to X \) is a nonconstant morphism of curves, there is a natural Artin character \( \tilde{\chi} = h^*\chi \) on \( \tilde{X} \) obtained by pulling back the abelian covering of \( X \) along \( h \). On divisors, \( \tilde{\chi} \) can be defined as \( \tilde{\chi}(D) = \chi(h_*D) \). Clearly, if \( \chi \) is unramified, then \( \tilde{\chi} \) is too, and more generally, \( f(\tilde{\chi}) = h^*f(\chi) \).
- Assume that \( q \) is odd. The Legendre symbol \( \left( \frac{\cdot}{q} \right) \) on \( \mathbb{P}^1 \), which sends the point of abscissa \( x \) to \( 1, -1, \) or \( 0 \) according as whether \( x \) is a quadratic residue, a quadratic nonresidue or \( 0, \infty \), extends to the nontrivial Artin character \( \chi_2 \) defined by the ramified quadratic covering \( \mathbb{P}^1 \to \mathbb{P}^1: x \mapsto x^2 \). One has \( f(\chi_2) = (0) + (\infty) \).
- More generally, if \( X \) is a curve over \( \mathbb{F}_q \) and \( \varphi \) a nonconstant, rational function on \( X \), the Legendre symbol of \( \varphi \) extends to an Artin character on \( X \), namely \( \varphi^*\chi_2 \). Its conductor is the sum of the divisor of zeros of \( \varphi \) and its divisor of poles. In particular, \( \deg f(\varphi^*\chi_2) = 2 \deg \varphi \).

When \( \chi \) is nontrivial, Weil [33] has proved the following estimate for sums related to \( \chi \), as a consequence of the Riemann hypothesis for curves (see, for example, [24 §2] or [29 Chapter 9]). For any Artin character \( \chi \) of \( X \), let:

\[
S_X(\chi) = \sum_{P \in X(\mathbb{F}_q)} \chi(P).
\]
Lemma 6. If \( \chi \) is nontrivial and \( X \) is of genus \( g \), one has
\[
|S_X(\chi)| \leq (2g - 2 + \deg f(\chi)) \sqrt{q}.
\]

We can now easily deduce the following result, which forms the basis of the proofs in Section 5.

Theorem 7. Let \( h : \tilde{X} \to X \) be a nonconstant morphism of curves, and \( \chi \) be any nontrivial character of \( J(\mathbb{F}_q) \), where \( J \) is the Jacobian of \( X \). Assume that \( h \) does not factor through a nontrivial unramified morphism \( Z \to X \). Then
\[
(7) \quad \left| \sum_{P \in \tilde{X}(\mathbb{F}_q)} \chi(h(P)) \right| \leq (2g - 2) \sqrt{q}
\]
where \( g \) is the genus of \( \tilde{X} \). Furthermore, if \( q \) is odd and \( \varphi \) is a nonconstant rational function on \( \tilde{X} \), then
\[
(8) \quad \left| \sum_{P \in \tilde{X}(\mathbb{F}_q)} \chi(h(P)) \left( \frac{\varphi(P)}{q} \right) \right| \leq (2g - 2 + 2 \deg \varphi) \sqrt{q}.
\]

Proof. Denote also by \( \chi \) the Artin character of \( X \) extending the given character of \( J(\mathbb{F}_q) \). The left-hand side of (7) is then just \( |S_{\tilde{X}}(h^*\chi)| \), and we know that \( h^*\chi \) is an unramified Artin character of \( \tilde{X} \), so the inequality follows from Lemma 6 provided that we can prove that \( h^*\chi \) is nontrivial. But if it is a trivial character, \( h_* \) maps all divisors of \( \tilde{X} \) to the kernel of \( \chi \); this means that \( h \) factors through the unramified covering \( Z \to X \) defined by the kernel of \( \chi \), which is impossible by hypothesis. Hence inequality (7).

Similarly, the left-hand side of (8) is \( |S_{\tilde{X}}(\tilde{\chi})| \) for \( \tilde{\chi} \) the Artin character of \( \tilde{X} \) defined as the product of \( h^*\chi \) and \( \varphi^*\chi_2 \). This character cannot be trivial; otherwise, \( \varphi^*\chi_2 \) would be the inverse of \( h^*\chi \), and hence unramified, which it is not. Thus, Lemma 6 gives \( |S_{\tilde{X}}(\tilde{\chi})| \leq (2g - 2 + \deg h(\tilde{\chi})) \sqrt{q} \). Since \( h^*\chi \) is unramified, we have \( \deg f(\tilde{\chi}) = 2 \deg \varphi \), which concludes the proof. \( \square \)

5. Examples of well-distributed encodings

5.1. Icart’s function. In [21], Icart defined a family of deterministic functions to elliptic curves \( E : y^2 = x^3 + ax + b \) over finite fields \( \mathbb{F}_q \) such that \( q \equiv 2 \pmod{3} \). His map \( f : \mathbb{F}_q \to E(\mathbb{F}_q) \) is given by \( u \mapsto (x, y) \) with
\[
(9) \quad x = \left( v^2 - b - \frac{u^2}{27} \right)^{1/3} + \frac{u^2}{3} \quad \text{and} \quad y = ux + v,
\]
where \( v = (3a - u^4)/(6u) \). The image of 0 is chosen as the neutral element of the elliptic curve.

Icart showed that a point \((x, y)\) is the image of \( u \) if and only if
\[
(10) \quad u^4 - 6xu^2 + 6yu - 3a = 0.
\]
This makes it possible to give a simple geometric interpretation of Icart’s function (and other encodings of the same type, as listed in Table 1), as has been done in [16, 18, 10].

Indeed, let \( K = \mathbb{F}_q(E) \) be the function field of \( E \), and introduce the smooth projective curve \( C \) whose function field is the quartic extension \( L = K[u]/(P) \) of
$K$, where $P = u^4 - 6xu^2 + 6yu - 3a$ (this curve $C$ is the normalization of the algebraic correspondence from $\mathbb{P}^1$ to $E$ given by the closed subvariety of $\mathbb{P}^1 \times E$ defined by equation (10)). The inclusions $\mathbb{F}_q(u) \subset L$ and $K \subset L$ give rise to rational maps $g: C \to \mathbb{P}^1$ and $h: C \to E$ which are in fact morphisms, since these curves are smooth and complete. Then, Icart’s function can be described as $f(u) = h(g^{-1}(u))$. This is well-defined when $q \equiv 2$ (mod 3) because in that case, all elements in the base field $\mathbb{F}_q$ has a unique cube root, which ensures that $g$ induces a bijection from the set of points in $C(\mathbb{F}_q)$ that are not poles of $u$ to $\mathbb{A}^1(\mathbb{F}_q) = \mathbb{F}_q$ (indeed, the preimage $(u, x, y)$ of any $u \in \mathbb{A}^1(\mathbb{F}_q) = \mathbb{F}_q$ is then uniquely defined by (11)).

This geometric point of view makes it possible to express the character sum $S_f(\chi)$, for any character $\chi$ of $E(\mathbb{F}_q)$, in terms of the Artin character sum $S_C(h^*\chi)$ (they are the same up to a few “bad points”), and then to use Theorem 7 to show that Icart’s function is well-distributed.

**Theorem 8.** Let $f$ be Icart’s function (9). For any nontrivial character $\chi$ of $E(\mathbb{F}_q)$, the character sum $S_f(\chi)$ given by (11) satisfies:

$$|S_f(\chi)| \leq 12\sqrt{q} + 3.$$

**Proof.** The map $h: C \to E$ defined above is a nonconstant morphism of curves. Moreover, we know from the analysis of [16] that if $a \neq 0$, $C$ is of genus 7, and that the Galois closure of the quartic extension $\mathbb{F}_q(C)/\mathbb{F}_q(E)$ has Galois group $S_4$ (for $a = 0$, the discussion in analogous). It follows that $\mathbb{F}_q(C)/\mathbb{F}_q(E)$ has no nontrivial intermediate extension, and it is clearly unramified (because an unramified covering of an elliptic curve must be of genus 1). Thus, $h$ fulfills the hypotheses of Theorem 7 and we get

$$\left| \sum_{P \in C(\mathbb{F}_q)} \chi(h(P)) \right| \leq (2 \cdot 7 - 2)\sqrt{q} = 12\sqrt{q}.$$

Now recall that $g$ induces a bijection from $C(\mathbb{F}_q) \setminus \{\text{poles of } u\}$ to $\mathbb{F}_q$. Thus:

$$\sum_{P \in C(\mathbb{F}_q)} \chi(h(P)) = S_f(\chi) + \sum_{P \in c(\mathbb{F}_q)} \chi(h(P)).$$

It is shown in the proof of [10] Lemma 7 that $u$ has exactly 3 poles on $C$, hence the result. □

In other words, Theorem 8 asserts that $f$ is a $(12 + 3q^{-1/2})$-well-distributed encoding.

In particular, as a well-distributed encoding to a curve of genus 1, Icart’s function $f$ satisfies that $f^{\otimes s}$ is regular for $s \geq 2$. Since $f^{\otimes 2}$ is computable and samplable, it is admissible. Indeed, a sampling algorithm for $f^{\otimes 2}$ has the following form: to pick a random element $(u, v)$ in the preimage of $P \in E(\mathbb{F}_q)$, choose $v \in \mathbb{F}_q$ at random and compute the preimages of $P - f(v)$ by $f$ (there are at most 4 of them). Then choose $i \in \{1, 2, 3, 4\}$ at random and return the $i$-th element among the previously computed preimages if it exists. Otherwise, start over. It is easy to see that the expected number of iterations is bounded, and that the resulting distribution is exactly uniform in $(f^{\otimes 2})^{-1}(P)$. This algorithm generalizes to all examples of functions $f^{\otimes s}$ considered below in a straightforward way. Thus, we get
a new, simpler and conceptually different proof of the main result of [10], that

\[ m \mapsto f(h_1(m)) + f(h_2(m)) \]

is indifferentiable from a random oracle when \( h_1, h_2 \) are seen as random oracles to \( \mathbb{F}_q \).

We also get more general results, since we have information about \( f \otimes s \) for \( s > 2 \), and the bounds we obtain are also sharper than those in [10]. More precisely, denoting the collision probability of \( f \) by \( \rho_f \), we have, by (3):

\[ \rho_f = q^{-2} \sum_{P \in E(\mathbb{F}_q)} \#f^{-1}(P)^2 \leq 4q^{-2} \sum_{P \in E(\mathbb{F}_q)} \#f^{-1}(P) = 4q^{-1}, \]

because points on \( E \) have at most 4 preimages. Hence, Theorem 1 and Theorem 3 give the following corollaries.

**Corollary 9.** For all \( P \in E(\mathbb{F}_q) \) and all \( s \), we have

\[ \left| \frac{N_s(P)}{q^s} - \frac{1}{\#E(\mathbb{F}_q)} \right| \leq \frac{(12 + 3q^{-1/2})^{s-2}(4\#E(\mathbb{F}_q)q^{-1} - 1)}{q^{s-1} \#E(\mathbb{F}_q)}. \]

**Corollary 10.** For all \( s \), the statistical distance between the distribution given by \( f \otimes s \) and the uniform distribution on \( E(\mathbb{F}_q) \) is bounded as

\[ \sum_{P \in E(\mathbb{F}_q)} \left| \frac{N_s(P)}{q^s} - \frac{1}{\#E(\mathbb{F}_q)} \right| \leq \frac{(12 + 3q^{-1/2})^{s-2}4\#E(\mathbb{F}_q)q^{-1} - 1}{q^{s-1}/2}. \]

Since \( \#E(\mathbb{F}_q) = q + O(q^{1/2}) \), the bounds of Corollaries 9 and 10 simplify as

\[ \left(11\right) \quad \left| \frac{N_s(P)}{q^s} - \frac{1}{\#E(\mathbb{F}_q)} \right| \leq \frac{3 \cdot 12^{s-2} + O(q^{-1/2})}{q^{s/2}} \]

and

\[ \left(12\right) \quad \sum_{P \in E(\mathbb{F}_q)} \left| \frac{N_s(P)}{q^s} - \frac{1}{\#E(\mathbb{F}_q)} \right| \leq \frac{\sqrt{3} \cdot 12^{s-1} + O(q^{-1/2})}{q^{s-1}/2}. \]

For \( s = 2 \), this gives a bound of the statistical distance of the form \( 12\sqrt{3}q^{-1/2} + O(q^{-1}) \), which is a significant improvement over the estimate from [10, §4.1]. We can refine this further by computing the collision probability precisely:

**Remark 11.** The Chebotarev density theorem gives the prevalence of points with any given number of preimages: the number of permutations in

\[ \text{Gal}(\mathbb{F}_q(C)/\mathbb{F}_q(E)) = S_4 \]

with exactly 1 (respectively 2, 4) fixed point(s) is 8 (respectively 6, 1), so the density of points with 1 (respectively 2, 4) preimages is 8/24 (respectively 6/24, 1/24). Using an effective version of the Chebotarev density theorem gives

\[ q^2 \rho_f = 1^2 \cdot \left( \frac{8q}{24} + O(\sqrt{q}) \right) + 2^2 \cdot \left( \frac{6q}{24} + O(\sqrt{q}) \right) + 4^2 \cdot \left( \frac{q}{24} + O(\sqrt{q}) \right). \]

Thus \( \rho_f = 2q^{-1} + O(q^{-3/2}) \), which allows us to drop the factors 3 and \( \sqrt{3} \) from (11) and (12), respectively.
5.2. Kammerer-Lercier-Renault’s functions. Kammerer, Lercier and Renault \cite{KLR} have recently introduced a series of new encodings based on the same principles as Icart’s function, namely solving curve equations in radicals. One such example is an encoding $f$ to hyperelliptic curves of genus 2 over fields $\mathbb{F}_q$ such that $q \equiv 2 \pmod{3}$ of the form

$$H: x^3 + (y + c)\left(3x + 2a + \frac{2b}{y}\right) = 0.$$  

The precise description of the encoding is rather complicated, and we refer the reader to \cite{KLR} §3.2.2 for details, but the geometric picture is the same as for Icart’s function. The parameter $u$ defining the encoding satisfies a relation of the form

$$4u^2(u^2 - 3y - a^2 - c)^3 + u^8 + \alpha u^4 + \beta u^2 + \gamma = 0,$$

where $\alpha, \beta, \gamma$ are constants in $\mathbb{F}_q$ defined in terms of $a, b, c$, which we assume are nonzero.

In particular, if $K = \mathbb{F}_q(x, y)$ is the function field of $H$, one can consider the extension $L = K[u]/(P)$ where $P$ is the polynomial of degree 8 given by the equation above. This defines a covering $h: C \to H$ of degree 8 by a certain smooth projective curve $C$, and the rational function $u$ on $C$ provides a morphism $g: C \to \mathbb{P}^1$ of degree 9 which induces a bijection on $\mathbb{F}_q$-rational points over $\mathbb{A}^1(\mathbb{F}_q) \setminus S$ where $S$ is a finite set of points shown in \cite{KLR} to be of size at most 75. The encoding $f: \mathbb{F}_q \to H(\mathbb{F}_q)$ is then defined as $u \mapsto h(g^{-1}(u))$ for $u \in \mathbb{F}_q \setminus S$, and is extended in some way to all $\mathbb{F}_q$.

Our machinery applies again to show that $f$ is a well-distributed encoding. Denote by $J$ the Jacobian of $H$, and fix an embedding $H \to J$.

**Theorem 12.** Let $f$ be the encoding function described above. For any nontrivial character $\chi$ of $J(\mathbb{F}_q)$, the character sum $S_f(\chi)$ given by (1) satisfies:

$$|S_f(\chi)| \leq 96\sqrt{q} + 759.$$  

**Proof.** The map $h: C \to H$ defined above is a nonconstant morphism of curves. Let us compute the genus of $C$.

Note first that $P(u)$ can be written as $Q(t)$ where $t = u^2$, which defines a factorization $C \to D \to H$, with $[D : H] = 4$. The discriminant of $Q$ is a polynomial of degree 12 in $y$, and each of its 12 roots corresponds to 3 ramified points on $H$, since each value of $y$ corresponds to 3 values of $x$ and above each such value of $x$ there is only one ramified point which is of index 2. Moreover, when regarded as a polynomial over $\mathbb{F}_q((1/y))$, the quartic $Q$ has a Newton polygon with integer slopes ($-3$ with length 1 and 1 with length 3). Thus, $D$ is unramified over points with $y = \infty$. All in all, the Riemann-Hurwitz formula gives $2g_D - 2 = 4 \cdot (2g_H - 2) + 3 \cdot 12 = 44$: $D$ is of genus 23.

Then, the quadratic covering $C \to D$ is ramified exactly at points such that $t = 0$ or $t = \infty$. At finite distance, this gives $\gamma = 0$, which is excluded, so all the ramification is at infinity. By the previous Newton polygon argument, over each point of $H$ with $y = \infty$ lie 4 points of $D$, one with $t = 0$ and three with $t = \infty$. And there are 2 such points of $H$, by another Newton polygon argument. Hence $2g_C - 2 = 2 \cdot (2g_D - 2) + 2 \cdot 4 = 96$, and $C$ is of genus 49.
Let us now show that \( h: C \to H \) does not factor nontrivially through an unramified covering. To see this, consider \( D_0 \to \mathbb{P}^1 \), the ramified covering of degree 4 defined by \( Q \) (which pulls back to \( D \to H \) along \( x: H \to \mathbb{P}^1 \)). We see as before that all points of \( D_0 \) ramified over \( \mathbb{P}^1 \) have ramification index 2. The group of automorphisms of \( D_0 \) generated by the ramification groups at these ramification points is, by construction, generated by transpositions. The quotient of \( D_0 \) by this group is an unramified cover of \( \mathbb{P}^1 \) and is therefore equal to \( \mathbb{P}^1 \). Thus, the monodromy group of the covering \( D_0 \to \mathbb{P}^1 \) is a transitive subgroup of \( S_4 \) generated by transpositions, hence all of \( S_4 \).

By inspection of the ramification of \( x: H \to \mathbb{P}^1 \), it follows that \( D \to H \) also has \( S_4 \) as its monodromy group. In particular, it has no quadratic subcovering. Now suppose \( h: C \to H \) factors through some abelian unramified extension \( Z \to H \), which we can assume is quadratic. Then the function fields \( \mathbb{F}_q(Z) \) and \( \mathbb{F}_q(D) \) are everywhere linearly disjoint over \( \mathbb{F}_q(H) \) (i.e., all of their embeddings in some algebraic closure of \( \mathbb{F}_q(H) \) are linearly disjoint). Thus \( \mathbb{F}_q(C) = \mathbb{F}_q(D) \otimes_{\mathbb{F}_q(H)} \mathbb{F}_q(Z) \), and in particular, \( C \to D \) is the pullback of \( Z \to H \) along \( D \to H \). This implies that \( C \to D \) is unramified, which we know is not the case.

Thus, \( h \) does not factor nontrivially through an abelian unramified covering, and hence fulfills the hypotheses of Theorem \( [\text{??}] \). We get

\[
\left| \sum_{P \in C(\mathbb{F}_q)} \chi(h(P)) \right| \leq (2g_C - 2)\sqrt{q} = 96\sqrt{q}.
\]

Now recall that \( g \) induces a bijection from \( C(\mathbb{F}_q) \setminus g^{-1}(S \cup \{\infty\}) \) to \( \mathbb{F}_q \setminus S \). Thus:

\[
\sum_{P \in C(\mathbb{F}_q)} \chi(h(P)) = \sum_{u \in \mathbb{F}_q \setminus S} \chi(f(u)) + \sum_{P \in g^{-1}(S \cup \{\infty\})} \chi(h(P))
= S_f(\chi) - \sum_{u \in S} \chi(f(u)) + \sum_{P \in g^{-1}(S \cup \{\infty\})} \chi(h(P)).
\]

Since \( \#S \leq 75 \) and \( g \) is of degree 9, we get

\[
|S_f(\chi)| \leq 96\sqrt{q} + 9 \cdot 76 + 75 = 96\sqrt{q} + 759
\]
as required. \( \square \)

In other words, \( f \) is a \((96 + 759g^{-1/2})\)-well-distributed encoding to \( H \). In particular, as a well-distributed encoding to a curve of genus 2, it satisfies that \( f^{\otimes s} \) is regular for any \( s \geq 3 \). Thus, \( f^{\otimes 3} \) is regular and clearly also computable and samplable, so the following construction

\[
m \mapsto f(h_1(m)) + f(h_2(m)) + f(h_3(m)) \in J(\mathbb{F}_q)
\]
is indifferentiable from a random oracle when \( h_1, h_2, h_3 \) are seen as random oracles to \( \mathbb{F}_q \). This is the first example of an efficient, well-behaved hash function to the Jacobians of a large family of curves of genus 2.

We now estimate (quite coarsely) the collision probability for \( f \): since \( h \) is of degree 8, any given point on \( H \) has at most 8 preimages by \( f \). Thus,

\[
\rho_f = q^{-2} \sum_{D \in J(\mathbb{F}_q)} \#f^{-1}(D)^2 \leq 8q^{-2} \sum_{D \in J(\mathbb{F}_q)} \#f^{-1}(D) = 8q^{-1}
\]

and so \( q \rho_f \leq 8 \) as required. So, now Theorem \( \boxed{[\text{??}]} \) and Theorem \( \boxed{[\text{??}]} \) give the following estimates.
Corollary 13. For all $D \in J(\mathbb{F}_q)$ and all $s$, we have
\[
\left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right| \leq \frac{8(96 + 759q^{-1/2})^{s-2}}{q^{s/2}}.
\]

Corollary 14. For all $s$, the statistical distance between the distribution given by $f^{\otimes s}$ and the uniform distribution on $J(\mathbb{F}_q)$ is bounded as
\[
\sum_{D \in J(\mathbb{F}_q)} \left| \frac{N_s(D)}{q^s} - \frac{1}{\#J(\mathbb{F}_q)} \right| \leq \sqrt{8} \cdot (96 + 759q^{-1/2})^{s-1} \sqrt{\#J(\mathbb{F}_q)} / q^{s/2}.
\]

Using that $\#J(\mathbb{F}_q) = q^2 + O(q^{3/2})$ one can also obtain simplified versions of Corollaries 13 and 14 similar to the bounds (11) and (12).

Of course, we have considered only one of the encodings from [23], but the same technique applies to all of them. In some cases, it is even much easier to apply. For example, in the case of the encoding to hyperelliptic curves $H_a: y^2 = x^{2d} + x^d + a$, the covering curve is $H_a$ itself (the parameter $u$ is in fact just $y - x^d \in \mathbb{F}_q(x,y)$), so the hypotheses of Theorem 7 are trivially verified.

5.3. Shallue-Woestijne-Ulas’s function. The first published type of encoding functions to ordinary elliptic curves, the functions of Shallue and van de Woestijne [30], have a rather different geometric interpretation than Icart-like encodings, but they can nevertheless be proved to be well-distributed by essentially the same techniques.

Here, we consider the simplified Shallue-Woestijne-Ulas encoding over fields $\mathbb{F}_q$ with $q \equiv 3 \pmod{4}$, as introduced in [10] with the sign tweak from [18]. The function is based on the following observation. If we let $g(x) = x^3 + ax + b \in \mathbb{F}_q[x]$ with $ab \neq 0$, and define
\[
X_2(u) = -\frac{b}{a} \left( 1 + \frac{1}{u^4 - u^2} \right), \quad X_3(u) = -u^2 X_2(u),
\]
and
\[
Z(u) = u^3 g(X_2(u)),
\]
then we have $Z(u)^2 = -g(X_2(u)) \cdot g(X_3(u))$.

Let $S = \{0,1,-1\} \cup \{\text{roots of } g(X_j(u)) = 0, j = 2,3\}$. For any $u \notin S$, $X_2(u)$ and $X_3(u)$ are well-defined and nonzero. Since $-1$ is a quadratic nonresidue in $\mathbb{F}_q$, this implies that for any $u \in \mathbb{F}_q \setminus S$, exactly one of $g(X_2(u))$ or $g(X_3(u))$ is a square. Therefore, we can define an encoding function $f$ to the elliptic curve $E: y^2 = x^3 + ax + b$ by
\[
f(u) = \left( X_j(u) ; (-1)^j \sqrt{g(X_j(u))} \right),
\]
where $j = 2$ or 3 is the index such that $g(X_3(u))$ is a square, and $\sqrt{\cdot}$ is the standard square root in $\mathbb{F}_q$, given by exponentiation by $(q + 1)/4$ (thus, the $y$-coordinate is a quadratic residue if $j = 2$ and a quadratic nonresidue if $j = 3$).
As discussed in [18], this encoding function admits the following geometric interpretation. It is easy to see that for all \( u \in \mathbb{F}_q \setminus \{-1, 0, 1\} \),
\[
\begin{align*}
x &= X_2(u) \iff u^4 - u^2 + \frac{1}{\omega} = 0, \\
x &= X_3(u) \iff u^4 - \omega u^2 + \omega = 0,
\end{align*}
\]
where \( \omega = \frac{q}{2} x + 1 \). Thus, we can introduce coverings \( h_j : C_j \to E, \; j = 2, 3 \), by the smooth projective curves whose function fields are the extensions of \( \mathbb{F}_q(x, y) \) defined respectively by \( u^4 - u^2 + 1/\omega = 0 \) and \( u^4 - \omega u^2 + \omega = 0 \). The parameter \( u \) is a rational function on each of the \( C_j \) giving rise to morphisms \( g_j : C_j \to \mathbb{P}^1 \), such that any point in \( \mathbb{A}^1(\mathbb{F}_q) \setminus S \) has exactly two preimages in \( C_j(\mathbb{F}_q) \) for one of \( j = 2, 3 \), and none in the other.

If \( u \in \mathbb{F}_q \setminus S \) has its preimages in \( C_j(\mathbb{F}_q) \), those preimages are conjugate under \( y \mapsto -y \), so that exactly one of them satisfies \( \left( \frac{u}{q} \right) = (-1)^j \). Let \( P \in C_j(\mathbb{F}_q) \) be that preimage. Then, \( f(u) = h_j(P) \). This geometric interpretation is enough to apply Theorem 7 and establish that \( f \) is well-distributed.

**Theorem 15.** Let \( f \) be the encoding described above. For any nontrivial character \( \chi \) of \( E(\mathbb{F}_q) \), the character sum \( S_f(\chi) \) given by (11) satisfies:
\[
|S_f(\chi)| \leq 52\sqrt{q} + 151.
\]

**Proof.** In light of the previous discussion, the character sum \( S_f(\chi) \), when restricted to parameters \( u \) in \( \mathbb{F}_q \setminus S \), can be written as
\[
\sum_{u \not\in S} \chi(f(u)) = \sum_{P \in C_j(\mathbb{F}_q) \setminus S_j} \chi(h_2(P)) + \sum_{P \in C_j(\mathbb{F}_q) \setminus S_3} \chi(h_3(P)),
\]
where \( S_j = g_j^{-1}(S \cup \{ \infty \}) \). To estimate such sums, observe that:
\[
\sum_{P \in C_j(\mathbb{F}_q)} \chi(h_j(P)) \cdot \left( \frac{1 + (-1)^j \left( \frac{u}{q} \right)}{2} \right)
\]
\[
= \sum_{P \in C_j(\mathbb{F}_q)} \chi(h_j(P)) + \frac{1}{2} \sum_{P \in C_j(\mathbb{F}_q)} \chi(h_j(P)) 
\]
\[
= \sum_{P \in C_j(\mathbb{F}_q)} \chi(h_j(P)) + \frac{1}{2} \sum_{P \in C_j(\mathbb{F}_q) \setminus S_j} \chi(h_3(P)).
\]
The first sum on the right-hand side of (14) is almost what we want (up to a bounded number of “bad terms”) and the second sum on the right-hand side contains at most \( 3 \cdot 4 = 12 \) terms.

Furthermore, the left-hand side of (14) is directly estimated using Theorem 7.
Indeed, by the Eisenstein criterion, \( h_2 \) and \( h_3 \) are totally ramified over points in \( H \) such that \( \omega = 0 \) (that is, \( x = -b/a \)), so they cannot factor through any unramified covering of \( E \). Hence, Theorem 7 applies and gives
\[
\sum_{P \in C_j(\mathbb{F}_q)} \chi(h_j(P)) \cdot \left( \frac{1 + (-1)^j \left( \frac{u}{q} \right)}{2} \right) \leq (2g_{C_j} - 2 + \deg y)\sqrt{q},
\]
where \( g_{C_j} \) is the genus of \( C_j \), and \( \deg y \) is the degree of \( y \) as a rational function on \( C_j \). Clearly, \( \deg y = [\mathbb{F}_q(x, y, u) : \mathbb{F}_q(x, y)] \cdot [\mathbb{F}_q(x, y) : \mathbb{F}_q(y)] = 4 \cdot 3 = 12 \).
Furthermore, to compute \( g_{C_j} \), note that in addition to the totally ramified points
mentioned previously, \( C_j \to E \) has ramification type \((2,2)\) at points with \( \omega = 4 \) and at infinity, and is unramified elsewhere. Thus, the Riemann-Hurwitz formula gives \( 2g_{C_j} - 2 = 0 + 2 \cdot 3 + 2 \cdot (1+1) + 2 \cdot (1+1) = 14 \): the curves \( C_j \) are of genus 8. Thus:

\[
\left| \sum_{P \in C_j(\mathbb{F}_q)} \chi(h_j(P)) \cdot \left( 1 + (-1)^j \left( \frac{2}{q} \right) \right) \right| \leq 26 \sqrt{q}.
\]

Plugging this estimate back into (13) using (14), we get:

\[
\left| \sum_{u \not\in S} \chi(f(u)) \right| \leq (26 \sqrt{q} + \#S_2 + 6) + (26 \sqrt{q} + \#S_3 + 6)
\]

\[= 52 \sqrt{q} + 12 + \#S_2 + \#S_3.\]

Thus, \( |S_f(\chi)| \leq 52 \sqrt{q} + 12 + \#S_2 + \#S_3 + \#S \). Now \( \#S \leq 3 + 2 \cdot 12 = 27 \), and since \( g_j \) is a map of degree 2, \( \#S_j \leq 2(\#S + 1) \leq 56 \), which concludes the proof.

Thus, we see from Theorem 15 that the simplified Shallue-Woestijne-Ulas encoding is \((52 + 151q^{-1/2})\)-well-distributed. As in Sections 5.1 and 5.2, using Theorem 1 and Theorem 3, we can deduce precise bounds on the maximum deviation of functions of the form \( f^{\otimes s} \) and on the statistical distance of the distribution they define on \( E(\mathbb{F}_q) \) and the uniform distribution.

In particular, we get that \( f^{\otimes s} \) is regular for \( s \geq 2 \). Since \( f^{\otimes 2} \) is clearly computable and samplable, it is admissible, and we obtain that

\[ m \mapsto f(h_1(m)) + f(h_2(m)) \]

is indifferentiable from a random oracle when \( h_1, h_2 \) are seen as random oracles to \( \mathbb{F}_q \).

Once again, the method generalizes to other SWU-like encodings, such as the Ulas encoding to hyperelliptic curves of the form \( y^2 = x^5 + ax + b \).

6. Pseudorandomness of Bits

The previous sections have focused on establishing regularity results for functions of the form \( f^{\otimes s} \) when \( f \) is a deterministic encoding to an elliptic or hyperelliptic curve and \( s \) is large enough (at least greater than the genus of the target curve). We now turn to a different problem: we would like to investigate the uniformity of \( f \) itself.

To fix ideas, let \( f \) be Icart’s function (the arguments adapt to other encodings easily). It is proved in [16, 18] that \( f(\mathbb{F}_q) \) consists of about \( 5/8 \) of the points of the target elliptic curve, so it is easy to construct a distinguisher between points constructed with \( f \) and points picked at random, by checking whether the point is in \( f(\mathbb{F}_q) \) or not (which can be done in polynomial time by computing the roots of (10)). If we have \( k \) points to check, the distinguisher succeeds with probability roughly \( 1 - (5/8)^k \). The same can be done if we only have the \( x \)-coordinate of the given points.
Suppose, however, that a device leaks only a fraction of the bits of $x$. Is it still possible to distinguish between points coming from $f$ and random points? What we can show is that it is in fact impossible if we are given less than half of the bits.

More precisely, let $q = p$ be a prime number with $p \equiv 2 \pmod{3}$. In particular, we identify the elements of $\mathbb{F}_p$ with the integers from the set $\{0, \ldots, p-1\}$. Given a binary string $\Sigma$, we denote by $R_f(\Sigma)$ the number of $u \in \mathbb{F}_p^*$ for which the least significant bits of the binary representation of the $x$-coordinate of $f(u)$ coincide with $\Sigma$.

**Theorem 16.** Let $f$ be Icart’s function [9]. For any bit string $\Sigma$ of length $k$, we have

$$R_f(\Sigma) = p \cdot 2^{-k} + O\left(p^{1/2} \log p \right)$$

and the implied constant in the big-$O$ is universal.

**Proof.** Let us consider the curve

$$C : \left(x - \frac{u^2}{3}\right)^3 = \left(\frac{3a - u^4}{6u}\right)^2 - \frac{b - u^2}{27}.$$ 

Clearly, for every $u \in \mathbb{F}_p^*$ there is a unique point $(u, x) \in C(\mathbb{F}_p)$ and the corresponding $x$ is exactly the $x$-coordinate $f(u)$. We consider the character sums

$$T_f(\psi) = \sum_{(u, x) \in C(\mathbb{F}_p)} \psi(x),$$

where $\psi$ is an additive character of $\mathbb{F}_p$. By the Bombieri bound of character sums along a curve [4], we see that

$$T_f(\psi) = O(p^{1/2}).$$

Let $s$ be the integer formed by $\Sigma$. We now note that the least significant bits of the binary representation of the $x \in \mathbb{F}_p$ coincide with $\Sigma$ if and only if we have

$$2^{-k}(x - s) \equiv z \pmod{p}$$

for some integer $z$ with $0 \leq z < p2^{-k}$. In particular, $R_f(\Sigma)$ counts the number of $u \in \mathbb{F}_p^*$ for which the ration $x/p$ for $x$-coordinate of $f(u)$ belongs to an interval of length $2^{-k} + O(1/p)$ on the unit torus $\mathbb{R}/\mathbb{Z}$.

We now combine (15) with the classical Erdős-Turán inequality (see, for example, [14, Theorem 1.21]) that relates the uniformity of distribution to character sums and implies that for any interval on $\mathbb{R}/\mathbb{Z}$ of length $\lambda$ there are $\lambda p + O(p^{1/2} \log p)$ of the above ratios $x/p$ that fall into this interval.

This immediately implies that the deviation of the number of solutions to (16) from the expected number of $p2^{-k}$ is $O(p^{1/2} \log p)$.

In particular, if $k \leq (1/2 - \varepsilon) \log p$, then for large enough $p$, the quantity $R_f(\Sigma)$ is independent of $\Sigma$ up to negligible deviations. This implies that the top $(1/2 - \varepsilon) \log p$ bits of the $x$-coordinate are indistinguishable from a random bit string of the same length. \qed
