Stabilizing Predictors for Weakly Unstable Correctors

By Hans J. Stetter

1. Introduction. It is well known that Milne-Simpson's method

(1)
$$y_{n+2} = y_n + \frac{h}{3}(f_n + 4f_{n+1} + f_{n+2})$$

should not be used for the numerical integration of y' = f(x, y) if $f_y < 0$ along the true solution y(x) although the solution of (1) converges to y(x) for fixed finite x as $h \to 0$ (see, e.g., [1]). In fact, rapid oscillations, with an amplitude increasing exponentially as the numerical integration proceeds, will supersede the values approximating y(x) and eventually destroy the meaningfulness of the computation. This "weak unstability" occurring with (1) and similar algorithms has been well, analyzed (e.g., [1, p. 248 ff.]) and procedures have been suggested to weaken its effect (e.g., [2]). We will show in this paper that it is quite easy to completely eliminate its cause: The combination of a judiciously chosen predictor with the weakly unstable corrector constitutes a strongly stable algorithm *if the corrector is not iterated*.

2. Analysis. Consider the k-step scheme

(2)
$$\rho(E)y_n - h\sigma(E)f_n = 0,$$

where $\rho(z) := \sum_{\nu=0}^{k} \alpha_{\nu} z^{\nu}, \alpha_{k} = 1; \sigma(z) := \sum_{\nu=0}^{k} \beta_{\nu} z^{\nu}; Ey_{n} := y_{n+1}; f_{n} := f(x_{n}, y_{n}).$ (2) is called D-stable¹ or stable for $h \to 0$ if all zeros of ρ are in $|z| \leq 1$ and no

(2) is called D-stable or stable for $h \to 0$ if all zeros of ρ are in $|z| \ge 1$ and no multiple zeros are on |z| = 1. (2) is of order p if, for a sufficiently differentiable function y,

$$\rho(E_h)y(x) - h\sigma(E_h)y'(x) = O(h^{p+1}),$$

where $E_h y(x) := y(x + h)$.

It is well known (e.g., [1]) that the sequence y_n generated by a D-stable scheme (2) of order $p \ge 1$ converges in an obvious sense to the solution y(x) of y' = f(x, y) as $h \to 0$. It is more difficult to predict the behavior of the y_n for finite h as weak instabilities may occur.

Denoting by $\zeta_{\nu}(H)$, $\nu = 1(1)k$, the zeros of the polynomial

(3)
$$\varphi(z, H) := \rho(z) - H\sigma(z),$$

we know from [1, p. 238], that for a scheme (2) of order p there is one zero, which we will always denote by $\zeta_1(H)$, which satisfies

(4)
$$\zeta_1(H) = e^H + O(H^{p+1}).$$

For a given value of H (real) we will call a D-stable scheme (2) strongly stable if²

¹ For Dahlquist-stable (cf. [3]).

² See Remark at the end of this section.

(5)
$$|\zeta_{\nu}(H)| \leq \zeta_{1}(H), \quad \nu = 2(1)k,$$

and weakly unstable otherwise.

Each D-stable scheme is strongly stable for H = 0, by continuity there will be a largest number $H^+ \ge 0$ and a smallest number $H^- \le 0$ such that (2) is strongly stable for each H from the *stability interval* $[H^-, H^+]^2$

It is evident for constant $g(x) := f_y(x, y(x))$ and confirmed by experience for variable g that the solution y_n of (2) simulates the behavior of y(x) if hg remains within the stability interval. For a weakly unstable scheme (e.g., Milne-Simpson's method (1)) $H^- = 0$ and the method should not be used for g < 0.

If $\beta_k \neq 0$, (2) defines y_{n+k} implicitly and is usually replaced by the *predictor*-corrector scheme³

(6)
$$y_{n+k}^{(0)} = -\sum_{\nu=0}^{k-1} \alpha_{\nu}^{*} y_{n+\nu} + h \sum_{\nu=0}^{k-1} \beta_{\nu}^{*} f_{n+\nu},$$
$$y_{n+k}^{(i)} = -\sum_{\nu=0}^{k-1} \alpha_{\nu} y_{n+\nu} + h \left(\sum_{\nu=0}^{k-1} \beta_{\nu} f_{n+\nu} + \beta_{k} f(x_{n+k}, y_{n+k}^{(i-1)}) \right), \quad i = 1(1)m.$$

A simple computation shows that for the algorithm (6) the polynomial (3) is transformed into⁴

(7)
$$\varphi^m(z, H) := (1 - B^m)(\rho(z) - H\sigma(z)) + B^m(1 - B)(\rho^*(z) - H\sigma^*(z))$$

with $B := H\beta_k$, $\rho^*(z) := \sum_{\nu=0}^k \alpha_{\nu} z^{\nu}$, $\alpha_k^* = 1$, $\sigma^*(z) := \sum_{\nu=0}^{k-1} \beta_{\nu} z^{\nu}$. Obviously $\lim_{m\to\infty} \varphi^m(z, H) = \varphi(z, H)$ if |B| < 1.

Assume that the predictor is of order $q \ge 0$. It is clear from (3), (4), and (7) that the zeros ζ_r^m of φ^m satisfy (after a suitable ordering)

(8)
$$\zeta_1^{m}(H) = e^H + O(H^{p+1}) + O(H^{q+m+1}),$$
$$\zeta_{\nu}^{m}(H) = \zeta_{\nu}(H) + O(H^m).$$

For all weakly unstable schemes of practical importance the violation of (5) for H < 0 is a *first-order effect in* H, hence only the zeros ζ_{ν}^{1} of φ^{1} may possibly not share the undesirable behavior of the ζ_{ν}^{5} . Therefore we may restrict our considerations to the case m = 1; we will—for given weakly unstable schemes—attempt to select (ρ^{*}, σ^{*}) such that the stability interval for φ^{1} has H = 0 as an interior point.

Remark: Some authors (e.g., [5]) replace (5) by $|\zeta_r(H)| \leq 1$ in the definition of a stability interval. This seems not appropriate since, e.g., a 2-step scheme with $\zeta_2(H) = -1 - H/2 + O(H^2)$ will also generate oscillations growing exponentially relative to the true solution if used for y' = -y.

3. Selection of the Predictor. From now on we will only consider the polynomial $\varphi^1(x, H)$ and its zeros $\zeta_{\nu}^{-1}(H), \nu = 1(1)k$, hence we will omit the superscript 1. Furthermore we define $\zeta_{\nu 0} := \zeta_{\nu}(0)$.

³ If the predictor reaches back farther than the corrector the degree k of the corrector has to be formally raised accordingly.

⁴ This assumes a $P(EC)^{m}E$ algorithm (cf. [4]); for a $P(EC)^{m}$ algorithm the situation is more complicated. See footnote 5, however.

⁵ Since (8) holds equally for $P(EC)^m$ algorithms (see [4]) our conclusion is also true for this case.

If $|\zeta_{\nu_0}| < 1$ for a certain $\nu > 1$, (5) has to hold in a full vicinity of H = 0 by continuity. Therefore it suffices to consider $\nu \in W := \{\nu : 2 \leq \nu \leq k, |\zeta_{\nu_0}| = 1\}$. For $\nu \in W$, let

(9)
$$|\zeta_{\nu}(H)| = 1 + A_{\nu}H + B_{\nu}H^{2} + O(H^{3}).$$

As $p \ge 2$ in all cases of interest, (4) and (5) yield the following necessary condition:

(10)
(a)
$$A_{\nu} = 1,$$

(b) $B_{\nu} \leq \frac{1}{2},$ for $\nu \in W.$

If the equality is excluded in (10b), condition (10) is sufficient as well to guarantee a stability interval with $H^- < 0$, $H^+ > 0$. (For $B = \frac{1}{2}$, the third order terms would have to be investigated.) To find expressions for the A_r and B_r we derive, from

$$\varphi^{1}(z, H) = [\rho(z) - H(\sigma(z) - \beta_{k} \rho^{*}(z)) - H^{2}\beta_{k} \sigma^{*}(z)](1 - B),$$
(11)
$$\zeta_{\nu}(H) = \zeta_{\nu 0} + H \cdot \frac{\tau_{\nu}}{\rho_{\nu}'} + H^{2}[-\rho_{\nu}'' \tau_{\nu}^{2}/2\rho_{\nu}' + \tau_{\nu} \tau_{\nu}' + \beta_{k} \rho_{\nu}' \sigma_{\nu}^{*}]/\rho_{\nu}'^{2} + O(H^{3}),$$

where $\tau(z) := \sigma(z) - \beta_k \rho^*(z)$, the prime denotes differentiation, and $\rho_{\nu} := \rho(\zeta_{\nu 0})$, etc. $\rho_{\nu}' \neq 0$ for a D-stable scheme and $\nu \in W$. Let $\zeta_{\nu 0} = e^{i\omega_{\nu}}$, then (10a) becomes

(12a)
$$\operatorname{Re}\left\{e^{-i\omega_{\nu}}\frac{\tau_{\nu}}{\rho_{\nu}'}\right\} = 1.$$

Since τ_{ν} is linear in the coefficients α_{ν}^* of ρ^* , for given ρ , σ , condition (10a) takes the form of a linear relation between the α_{ν}^* (which are assumed real) for each $\nu \in W$.

Condition (10b) becomes an inequality which is quadratic in the α_{ν}^{*} and linear in the β_{ν}^{*} : Using (12a) we have

where ψ_{ν} denotes the coefficient of H^2 in (11). Since the corrector must not be iterated according to our analysis, the order q of the predictor must be no less than p-1if the original order p of the corrector is to be maintained for the predictor-corrector scheme (6) with m = 1 (see, e.g., [1, p. 259 ff.]). The requirement of a certain order q for the predictor generates q + 1 homogeneous linear relations between the α_{ν}^* and β_{ν}^* . Thus the following procedure seems appropriate for the determination of a suitable (ρ^*, σ^*) for a given weakly unstable scheme (2): Evaluate (12a) in terms of the α_{ν}^* , then express ρ^* and σ^* in terms of the free parameters (if any) which are left after accounting for the order relations and (12a). Then interpret (12b) as a restriction in the space of these free parameters (or check its validity).

Remark: The same considerations can be carried through for $P(EC)^1$ algorithms. However, the details are more involved.

4. Application. For Milne-Simpson's 2-step scheme (1) we have $\rho = z^2 - 1$, $\sigma = (z^2 + 4z + 1)/3$, p = 4, and $\zeta_{20} = -1$. As we have to require q = 3, it seems futile to look for a stabilizing predictor with k = 2 since the order relations alone

determine ρ^* , σ^* in this case:

(13)
$$\rho^* = z^2 + 4z - 5, \quad \sigma^* = 4z + 2.$$

Yet by a marvelous coincidence this is a predictor which does the trick:

$$-1 \cdot \frac{\sigma(-1) + \beta_2 \rho^*(-1)}{\rho'(-1)} = +1,$$

$$-\psi(-1) + \frac{1}{2} \left(\frac{\tau_2}{\rho_2'}\right)^2 = -\frac{1}{3} < 1.$$

Therefore the algorithm

(14) $y_{n+2}^{(0)} = -4y_{n+1}^{*} + 5y_n + 2h(2f_{n+1} + f_n),$ $y_{n+2} = y_n + \frac{h}{3}(f_{n+2}^{(0)} + 4f_{n+1} + f_n)$

is a genuine 2-step method of order 4 which is strongly stable for arbitrary H (as it turns out), i.e., it can be safely used for g < 0 as well as for g > 0. Numerical results which have been obtained with (14) are shown in Section 5.

Admitting 3-step predictors, we could at first try to achieve q = 4: All predictors

$$\rho^* = z^3 + (8 + \alpha_0^*)z^2 - 9z - \alpha_0^*,$$

$$\sigma^* = [(17 + \alpha_0^*)z^2 + (14 + 4\alpha_0^*)z - (1 - \alpha_0^*)]/3$$

are of order 4 (see, e.g., [6, p. 201]), so it seems that we have one parameter left for the satisfaction of (12). However, upon introduction of the above ρ^* into (12a), the parameter α_0^* drops out and the necessary condition cannot be satisfied: There is no stabilizing 3-step predictor of order 4. Among the 3-step predictors with q = 3the following one-parameter family is found to be stabilizing:

(15)
$$\rho^* = z^3 + (4 + \alpha_0^*)z^2 - 5z - \alpha_0^*, \\ \sigma^* = [(12 + \alpha_0^*)z^2 + (6 + 4\alpha_0^*)z + \alpha_0^*]/3, \qquad \alpha_0^* > -3.$$

For $\alpha_0^* = 0$, which is well within the stabilizing region, we recover our 2-step predictor (13). Since the error term of (15) is $h^4 y^{IV}/6$ independently of α_0^* there is no indication why one should not choose the simpler predictor (13) and discard the 3-step predictors.

5. Comparison with Runge-Kutta, Numerical Results. In the case of an equation y' = gy, g = const, the relative discretization error

$$e_{\mathbf{r}}(x_{\mathbf{n}}, h) := (y_{\mathbf{n}}(h) - y(x_{\mathbf{n}}))/y(x_{\mathbf{n}})$$

will behave approximately⁶ like $Cg^5(x - x_0)h^4$ with

(16)
$$C = \begin{cases} +\frac{1}{180} & \text{for the exact solution of (1),} \\ -\frac{1}{45} & \text{for the stabilized scheme (14),} \\ -\frac{1}{120} & \text{for the classical Runge-Kutta method.} \end{cases}$$

⁶ (16) takes into account the first term of the asymptotic expansion of the discretization error under the assumption that the initial errors are $O(h^{\delta})$. For the values of C, see, e.g., [1].

(with 2 <i>h</i>) $0053 \ 07526 + 18899 + 4237 \\ 299 \\ 19 \\ 1$	

Obviously, the stabilization of (1) has to be paid for by a loss in accuracy such that the stabilized version of (1) is less accurate than R.-K. However, basing the comparison on an equal number of evaluations of f for a given interval of integration (see [4]) we find that the error of (14) is only $\frac{1}{6}$ of that for R.-K. Hence we may expect that (14) is a rather effective fourth order method for the numerical integration of ordinary differential equations.

The following differential equations were solved by the predictor-corrector scheme (14) and by R.-K.: (a) y' = -y, (b) $y' = -y^2$, each with y(0) = 1, for $x \leq 20$. The value of y(h) for scheme (14) was computed by *one* execution of R.-K.; this introduces an error of $O(h^5)$.

It is clear that the usual Milne-Simpson algorithm would have failed on both equations over such a long interval.⁷ With algorithm (14) not the least sign of an oscillation or an undue round-off accumulation was found on either differential equation. As to be expected from (16), for eq. (a) the error with (14) was less than

⁷ Although for eq. (b) the oscillations will grow only like $h(x + 1)^{8/3}$ relative to the basic discretization error, this constitutes an intolerable disturbance for large x.

20% of that with R.-K. (and equal effort) throughout the interval and for all stepsizes used. Some numerical values are shown in Table 1.

For the nonlinear equation (b), the errors of (14) and R.-K. were practically equal for small stepsizes. For very large steps R.-K. was poorer, with decreasing hthe discretization error changed its sign and became smaller (see Table 2). (This effect is caused by the complicated error terms of R.-K. which contain various derivatives of different order.) Due to this unsystematic behavior of the discretization error Richardson-extrapolation was not applicable for R.-K. while it worked well for (14) where the error decreased like h^4 approximately for large and small h.

Acknowledgment. The preparation of this paper was stimulated through some results obtained by A. Neiss in a systematic experimental investigation on the effect of predictor-corrector interaction upon stability [7].
