Iterates of a Number-Theoretic Function

By Mohan Lal*

Abstract. Iterates of a function defined by the sum of the prime divisors of a number, where the multiple factors are counted multiply, are considered. The process of iteration is terminated at a prime. The density distribution of these primes is investigated empirically, for $N \leq 60000$ and it is found to be quite constant. ■

Introduction. Let $n = \prod p_i^{\alpha_i}$ be the representation of n as a product of distinct primes and define a function,

$$(1) \quad J(n) = \sum_i \alpha_i p_i.$$

Thus the function $J(n)$ is defined to be the sum of the prime divisors of n and the multiple factors are counted multiply. From (1) it follows that $J(n)$ is completely additive, for $J(mn) = J(m) + J(n)$.

For n , a prime, $J(p) = p$ and for n , a composite number, $J(n) < n$. For $n = 4$, $J(4) = 4$ and this is considered to be an exceptional case and thus the number 4 behaves like a prime.

The r th iterate of $J(n)$ is defined by

$$(2) \quad J_r(n) = J(J_{r-1}(n)) ; \quad J_1(n) = J(n).$$

When n is a prime, each successive iterate gives rise to the same prime and we may say that the process of iteration converges. In what follows we will assign a value of 1 to r , for $n = \text{prime}$. For composite numbers, r takes definite positive integral values for the iteration (2) to converge. Thus for $n = 8$, $r = 3$ since $J_1(8) = 6$; $J_2(8) = 5$; $J_3(8) = 5$. In this manner, we shall associate with an integer n , a function $R(n)$ which defines the minimum number of iterates of $J(n)$ required to transform it into a prime. Thus, we define $R(n) = r$ and so, $R(30) = 3$, $R(24) = 4$, $R(10) = 2$.

Naturally the question arises, "What can be said about $R(n)$?"

Still, another interesting problem related to the iterates of $J(n)$ could be stated as follows. Suppose we apply the iterates of $J(n)$ to all integers less than or equal to N , we obtain a set of primes which are distributed all over the interval. Then, if $n(p_i)$ is the number of primes p_i between 1 and N inclusive, "Does the ratio $n(p_i)/N$ approach a definite limit, as N approaches infinity, for all p_i ?" It should be stated that the prime $p = 3$ occurs only once and $n = 4$ is an exceptional case for which $R(4)$ is not defined in our context.

To find analytic solutions to these questions, which involve various partitions of a number into primes, would probably be difficult. In what follows we provide an empirical investigation of these problems.

We studied $R(n)$ and $J_r(n)$ for $n \leq 60000$, using a sieve method. In Table 1, we present the number of primes $n(p_i)$, for $5 \leq p_i \leq 59$ at steps of 5000. We note that for these 15 values of p_i , $n(p_i)/N$ is quite constant. Therefore, there is strong indication that the ratio $n(p_i)/N$ approaches a definite limit, as $N \rightarrow \infty$.

Further empirical study reveals that $n(p_i)$ is very roughly proportional to $N/(p_i \times \log p_i)$. This is shown in Table 2, where we tabulate

$$(3) \quad C(p_i) = p_i \times \log(p_i) \times n(p_i)/N$$

for $N = 20000, 40000$ and 60000 . The values of $C(p_i)$ are quite consistent for these three values of N .

As far as $R(n)$ is concerned, we note the empirical result that $R(n) \leq [\log(n)] + 3$, for $n \leq 60000$.

In conclusion, we might indicate, that though (3) describes the distribution $n(p_i)$ approximately, it is not entirely satisfactory, since it does not indicate why $n(p+2) > n(p)$, in the case of twin primes, except for $p = 5$. One wonders if the expression (3) has any basis, heuristic or otherwise. The constants $C(p_i)$ do vary considerably for these fifteen values.
