THRESHOLD GROWTH DYNAMICS

JANKO GRAVNER AND DAVID GRIFFEATH

ABSTRACT. We study the asymptotic shape of the occupied region for monotone deterministic dynamics in d -dimensional Euclidean space parametrized by a threshold $\theta > 0$, and a Borel set $\mathcal{N} \subset \mathbb{R}^d$ with positive and finite Lebesgue measure. If A_n denotes the occupied set of the dynamics at integer time n , then A_{n+1} is obtained by adjoining any point x for which the volume of overlap between $x + \mathcal{N}$ and A_n exceeds θ . Except in some degenerate cases, we prove that $n^{-1}A_n$ converges to a unique limiting “shape” L starting from any bounded initial region A_0 that is suitably large. Moreover, L is computed as the polar transform for $1/w$, where w is an explicit *width* function that depends on $\mathcal{N}$ and θ .

It is further shown that L describes the limiting shape of wave fronts for certain cellular automaton growth rules related to lattice models of excitable media, as the threshold and range of interaction increase suitably. In the case of *box* (l^∞) neighborhoods on $\mathbb{Z}^2$, these limiting shapes are calculated and the dependence of their anisotropy on θ is examined. Other specific two- and three-dimensional examples are also discussed in some detail.

1. INTRODUCTION

For motivation, we begin by considering a simple cellular automaton (CA) on the two-dimensional integer lattice $\mathbb{Z}^2$. Let $N = \{(x_1, x_2) \in \mathbb{Z}^2: |x_1| \leq 1 \text{ and } |x_2| \leq 1\}$ be the so-called Moore neighborhood containing the origin $\mathbf{0}$ and the 8 lattice points closest to $\mathbf{0}$, and let $x + N$ be the translated neighborhood for $x \in \mathbb{Z}^2$. At each nonnegative integer time n , our automaton occupies a finite subset A_n of the lattice. This occupied set changes over time according to the following dynamics:

- (1.1) (i) If $x \notin A_n$ and $\#(A_n \cap (x + N)) \geq 3$, then $x \in A_{n+1}$;
 (ii) If $x \in A_n$, then $x \in A_{n+1}$.

In words, an unoccupied site becomes occupied next time if at least 3 of its 8 neighbors are occupied this time, while occupied sites are never vacated. This CA agrees with John Conway’s celebrated Game of Life (cf. [7, 12]) except for two changes that greatly simplify the evolution. First, “birth” in (1.1) requires *at least* 3 living neighbors whereas Life needs *exactly* 3. Second, “death” is impossible in (1.1), but plays a key role in the complexity of Conway’s dynamics.

Key words and phrases. Growth model, threshold dynamics, excitable medium, polar transform. This research was partially supported by research grants from the National Science Foundation.

Consequently our rule has two monotonicity properties, easily verified, that make it much more amenable to mathematical analysis. Namely, if we start from a finite set A at time 0 and let T denote the iterated transformation that gives rise to (1.1), then the following facts are self-evident:

$$(1.2) \quad A \subset TA;$$

$$(1.3) \quad \text{If } A \subset B, \text{ then } TA \subset TB.$$

That is, the occupied set can only grow, and if we start with more occupied sites initially then we have more occupied sites for all time.

So how does $A_n = T^n A$ evolve? Starting from a singleton (e.g., $\{0\}$), or a set with very small connected components, no changes are possible since the threshold for birth is 3. But suppose the initial configuration contains a sufficient local concentration of sites to promote birth at the boundary. For instance, choose $A = N$. Then A_n spreads over $\mathbb{Z}^2$ at a constant rate, as indicated by Figure 1, quickly attaining an octagonal shape. (Each shaded “ring” depicts two successive time steps.) Since asymptotic shape is the central theme of this paper, let us now present a precise formulation of the limiting behavior we wish to establish. It is most convenient to embed the lattice in Euclidean space. Then for any Borel $A \subset \mathbb{R}^d$, and $\varepsilon > 0$, write $A^\varepsilon = \{y \in \mathbb{R}^d : \|y - x\| \leq \varepsilon \text{ for some } x \in A\}$. ($\|\cdot\|$ is the Euclidean norm.) In this context, convergence of sets will be defined as follows.

Definition. A sequence of Borel sets $A_n \subset \mathbb{R}^d$ converges to a closed set $A \subset \mathbb{R}^d$ ($A_n \xrightarrow{H} A$) iff given any $\varepsilon > 0$, there is an $n_\varepsilon < \infty$ such that $A \subset A_n^\varepsilon$ and $A_n \subset A^\varepsilon$ for all $n \geq n_\varepsilon$.

This notion is usually called convergence in the *Hausdorff metric*. We require a closed limit set to ensure uniqueness.

Returning to our illustrative example, let $\mathcal{O}$ denote the octagonal region of $\mathbb{R}^2$ that is the closed convex hull of the 8 points: $(\pm\frac{1}{2}, 0)$, $(0, \pm\frac{1}{2})$, $(\pm\frac{1}{3}, \pm\frac{1}{3})$. Figure 1 indicates that as $n \rightarrow \infty$,

$$(1.4) \quad n^{-1} T^n N \xrightarrow{H} \mathcal{O}.$$

In words, the shape A_n spreads linearly with asymptotic shape $\mathcal{O}$. For this particular example the claimed convergence is easy to check because the exact form of the n th iterate is readily obtained by induction. Moreover, starting from any finite set A that contains a translate of N ,

$$(1.5) \quad n^{-1} T^n A \xrightarrow{H} \mathcal{O},$$

so the limit is independent of the initial configuration provided it is sufficiently large. Claim (1.5) follows quite easily from (1.2)–(1.4); for now, this argument is left as a little puzzle.

Note that the birth threshold in rule (1.1) equals $\frac{1}{3}$ the size of the neighbor set. Suppose next that we change to a 10-box neighbor set $N = \{(x_1, x_2) \in \mathbb{Z}^2 : |x_1| \leq 10 \text{ and } |x_2| \leq 10\}$, while increasing the threshold from 3 to $\theta = \frac{1}{3} \#N = \frac{1}{3}(21)^2 = 147$. Figure 2 shows the resulting pattern of growth starting from the new N . (Individual cells are smaller in the second figure than in the first.) Evidently the range-10 example also attains an asymptotic shape. The exact behavior of this CA is *much* more complicated than (1.1), however.

FIGURE 1

FIGURE 2

Although we will prove later that it *does* have an asymptotic shape, i.e., that $n^{-1}T^n A$ converges to a unique limit from all suitably large finite initial A , we do not know a straightforward way to characterize the limit, nor even whether it is a polygon.

The real message of Figure 2 is not the quagmire of large-scale lattice rules, but rather its “smoother” shape, suggesting a continuum limit as the threshold θ and range ρ of the ρ -box neighbor set increase appropriately. More specifically, for positive integer values of θ and ρ write

$$N_\rho = \{(x_1, x_2) \in \mathbb{Z}^2 : |x_1| \leq \rho \text{ and } |x_2| \leq \rho\},$$

and define $T = T_{\theta, \rho}$ on finite subsets of $\mathbb{Z}^2$ by

$$(1.6) \quad TA = \{x \in \mathbb{Z}^2 : \#(A \cap (x + N_\rho)) \geq \theta\} \cup A.$$

Assume that a sequence of thresholds θ_k and a sequence of ranges ρ_k both tend to ∞ in such a way that $\theta_k/\rho_k^2 \rightarrow \theta$. Then Riemann approximation suggests that transformations $\rho_k^{-1}T_{\theta_k, \rho_k}$ approach a limiting transformation $\mathcal{T} = \mathcal{T}_\theta$ on nice sets, with

$$(1.7) \quad \mathcal{T}A = \{x : |A \cap (x + \mathcal{N})| \geq \theta\} \cup A.$$

Here $\mathcal{N} = \{(x_1, x_2) \in \mathbb{R}^2 : |x_1| \leq 1 \text{ and } |x_2| \leq 1\}$ is the Euclidean box of side 2 centered at $\mathbf{0}$, and $|\cdot|$ denotes Lebesgue measure when applied to sets. The precise meaning of this convergence of transformations will be spelled out toward the end of the paper. But the idea is simple enough that this informal sketch should serve to motivate our study of *Euclidean threshold growth dynamics*: iteration of rule (1.7) or its extension to d -dimensional space and any Borel neighbor set $\mathcal{N}$ with $0 < |\mathcal{N}| < \infty$.

Our central problem, then, is as follows. Given $\theta > 0$ and a bounded Borel set $\mathcal{N} \subset \mathbb{R}^d$ of positive measure, with $\mathcal{T}$ defined by (1.7), is there a limit set $L \subset \mathbb{R}^d$ such that

$$(1.8) \quad n^{-1}\mathcal{T}^n A \xrightarrow{H} L$$

as $n \rightarrow \infty$, for all sufficiently large bounded initial sets $A \subset \mathbb{R}^d$, and is it possible to characterize L ? As we shall see, this problem can be solved in great

generality. Moreover, in specific examples such as the threshold-range limit corresponding to Figures 1 and 2 (i.e., $d = 2$, $\mathcal{N}$ = box of side 2, $\theta = \frac{4}{3}$), the asymptotic shape can be calculated quite explicitly. Most of the remainder of this introduction will be devoted to a discussion of our main result and a broad outline of its proof. But first, let us briefly digress to mention the initial motivation for this work: cellular automaton modeling of excitable media.

Mathematical models for excitable media attempt to capture and explain the key features of periodic wave transmission through environments such as a network or tissue. Since the pioneering work of N. Wiener and A. Rosenbluth [13] in the mid-1940s, a great many researchers across the spectrum of applied science have adopted various modeling frameworks, most notably partial differential equations, cellular automata, and coupled lattice maps. A common feature of many such models is the requirement that some threshold level of excitation occur in a neighborhood of a location in order for that location to become “excited” and conduct a pulse. Such activity is typically followed by a refractory period in which further excitation is inhibited. Physical systems that exhibit this basic phenomenology include neural networks, cardiac muscle, and the Belousov-Zhabotinsky (BZ) oscillating chemical reaction. In two dimensions such systems are typically characterized by the emergence of spatially-distributed stable “target” patterns or spirals.

Arguably the simplest dynamical system that emulates an excitable medium is a 3-stage, range-1, threshold-1 CA known as the *Greenberg-Hastings* (GH) model (cf. [8]). With the advent of effective computer visualization technology there has been a recent flurry of excitable CA modeling, based on the GH prototype but trying to approximate precise quantitative features of observed phenomena (e.g., curvature and wave velocity in the BZ reaction). To accomplish this, most experimentalists introduce several rather ad hoc parameters that are designed to generate an assortment of nonlinear effects.

Together with R. Fisch, we recently carried out a detailed experimental study of a 3-parameter family of simple GH-type rules [6]. The parameters are ρ : the range of interaction (assuming a box neighborhood); θ : the threshold number of excited neighbors required for a cell to become excited; and κ : the number of possible states (=colors) per cell. Here state 0 is “rested,” 1 is “excited,” and $2 \dots \kappa - 1$ are refractory. The refractory states update automatically each time, so κ governs the recovery time. A more detailed description of these GH dynamics will be presented in the last section of this paper.

Our main findings in [6] were two-fold. First we discovered that as one varies ρ , θ and κ , this family of models displays a remarkably complex phase portrait containing several cutoffs that divide the ergodic behavior of the infinite lattice dynamics into qualitatively distinct regimes. For instance, one regime is characterized by statistical noise, another by nucleation of stable spiral pairs, a third by clustering of aligned parades of wave fragments, and a fourth by global relaxation. See [6] for color computer graphics that illustrate these various forms of complex self-organization, and for an extensive bibliography of research on excitable media. The even more exotic dynamics of closely-related *cyclic cellular automaton* (CCA) models are also described and illustrated. IBM-compatible freeware [5] that facilitates GH and CCA experimentation is available from the authors.

Our second discovery was the emergence of curvature and limiting dynamics in excitable CA systems, as the threshold and range increase, with $\theta_k/\rho_k^2 \rightarrow \theta$. This *threshold-range scaling* is particularly appealing from a mathematical point of view since the limiting Euclidean evolutions are surprisingly amenable to rigorous analysis. For instance, one can investigate the geometry of wave fronts and spiral curves in the threshold-range limit. When θ is small, as it turns out, the asymptotic shapes of propagating Euclidean GH rings and spirals are precisely the same as the asymptotic shape (1.8) for threshold growth dynamics. This application was the original motivation for our present study; we will discuss it further at the conclusion of the paper.

Let us now turn to the strategy for proving a limiting shape theorem of the form (1.8). It is instructive to consider first the one-dimensional situation. The shape result is little more than an exercise when $d = 1$, but provides a useful template for the challenge of higher dimensions. Suppose that $\mathcal{N}$ is symmetric about 0, with $\sup \mathcal{N} = l < \infty$. If $\theta \geq \frac{1}{2}|\mathcal{N}|$, then starting from any bounded A growth is impossible beyond the extreme points of A , and so (1.8) holds with $L = \{0\}$ (i.e., the limiting shape is *trivial*). On the other hand, suppose $\theta < \frac{1}{2}|\mathcal{N}|$, and start from $A = [-l, l]$. Then with each iteration the occupied interval grows at both edges by a constant amount $w > 0$, where

$$w = \max\{x \geq 0: |(x + \mathcal{N}) \cap (-\infty, 0]| \geq \theta\}.$$

Hence $L = [-w, w]$ in this case. As in our first CA example, (1.3) implies the same limiting shape from any bounded A that contains a translate of $[-l, l]$. For general $\mathcal{N}$ in one dimension one needs to identify two edge velocities:

$$(1.9) \quad \begin{aligned} w^+ &= \max\{x \geq 0: |(x + \mathcal{N}) \cap (-\infty, 0]| \geq \theta\}; \\ w^- &= \max\{x \geq 0: |(-x + \mathcal{N}) \cap [0, \infty)| \geq \theta\}. \end{aligned}$$

If either set of x values is empty the corresponding max is defined to be 0. Whenever A contains a translate of $[-l, l]$, it is straightforward to check that (1.8) holds with $L = [-w^-, w^+]$. Further details are left to the reader. For the remainder of the paper we assume that $d \geq 2$.

Since L is determined by half-line velocities (1.9) in one dimension, it is natural to describe the limiting shape in higher dimensions by means of the asymptotic velocity $\alpha(u) = \alpha_L(u)$ for each unit vector u in the $d - 1$ dimensional sphere $\mathcal{S} = \mathcal{S}^{d-1} \subset \mathbb{R}^d$. That is to say,

$$L = \{\lambda u: u \in \mathcal{S}, 0 \leq \lambda \leq \alpha(u)\}.$$

This approach is well-established in the theory of *stochastic growth models*. Explicit computation of the limit shape is possible for a few processes, e.g., branching random walks in which case L is described by means of a Legendre transform [1], or internal diffusion limited aggregation [9] for which one can apply probabilistic harmonic analysis to prove that L is a Euclidean ball. More often, the subadditive ergodic theorem is used to prove existence of radial limits for the rate of growth. Various techniques are then employed to “patch together” the $\alpha(u)$ into a convex limiting shape. This strategy applies to Eden’s model [3] and other prototypes for random contagion; Durrett [2] gives a very nice introduction to the subject. It should be noted, however, that subadditivity rarely reveals quantitative information about the limiting shape, e.g., whether or not it is isotropic (i.e., a Euclidean ball). In §6 we will mimic the

stochastic approach to prove an implicit shape theorem for threshold growth on $\mathbb{Z}^d$. But for Euclidean threshold growth one can obtain a much more concrete representation.

The idea behind our identification of L in the Euclidean setting is quite simple, and familiar to researchers in the field of interface dynamics. Any growing cluster with an asymptotic shape becomes *locally flat* at its boundary. Since our threshold growth rule is effectively local, unoccupied sites near the boundary of $\mathcal{T}^n A$ eventually encounter a configuration that is virtually indistinguishable from a half-space. Given $u \in \mathcal{S}$, denote the half-space

$$(1.10) \quad H_u^- = \{x \in \mathbb{R}^d : \langle x, u \rangle \leq 0\}.$$

($\langle \cdot, \cdot \rangle$ is the Euclidean dot product.) In clear analogy with the one-dimensional case, H_u^- propagates at constant speed

$$(1.11) \quad w(u) = \max\{\lambda \geq 0 : |(\lambda u + \mathcal{N}) \cap H_u^-| \geq \theta\}.$$

Not surprisingly this *width function* w plays a key role in our evaluation of the limiting shape. But how do α and w “patch together”? Assume for simplicity that α is continuously differentiable ($\mathcal{C}^1$). The half-space encountered at the boundary in direction u is $H_{\nu(u)}^-$, where $\nu(u)$ denotes the (outward) normal to L at the point $\alpha(u)u$. This half-space has speed $w(\nu(u))$ in direction $\nu(u)$, which yields speed $w(\nu(u))/\langle u, \nu(u) \rangle$ in direction u . We conclude that

$$(1.12) \quad \alpha(u) = \frac{w(\nu(u))}{\langle u, \nu(u) \rangle}.$$

Since $\nu(u)$ depends on L , (1.12) determines the limiting shape *implicitly*. When $d = 2$ this formula is equivalent to a nasty differential equation for α (in polar coordinates, say). For many simple choices of $\mathcal{N}$ the solution exhibits singularities and bifurcations indicating that L may *not* be $\mathcal{C}^1$. In that case, how convincing is our heuristic? The solution to this quandary involves a representation of α , agreeing with (1.12) in the $\mathcal{C}^1$ case, in terms of the *polar transform*. For any $K \subset \mathbb{R}^d$, the *polar* of K is the set

$$(1.13) \quad K^* = \{x \in \mathbb{R}^d : \langle x, y \rangle \leq 1 \text{ for all } y \in K\}.$$

This is the mapping that takes the unit ball in a Banach space to the unit ball of the dual space. Also, for any continuous $f: \mathcal{S} \rightarrow [0, \infty]$, we denote the “shape corresponding to f ” as

$$(1.14) \quad K_f = \{\lambda u : u \in \mathcal{S}, 0 \leq \lambda \leq f(u)\}.$$

Recall that $L = K_\alpha$ by definition. For smooth α , (1.12) is equivalent to

$$(1.15) \quad L = K_{1/w}^*,$$

as explained in the Appendix to this paper (cf. (A.3)–(A.5)).

Our main goal is to demonstrate that Euclidean threshold growth dynamics attain a limiting shape L in great generality: if the polar of $K_{1/w}$ is either $\{0\}$ (trivial) or has full dimension d , then (1.8) holds with L given by formula (1.15). More precisely, we will prove the following result.

Theorem 1. Let $\mathcal{N} \in \mathcal{B}(\mathbb{R}^d)$ be a set (bounded or unbounded) with finite volume, and fix $0 < \theta < \infty$. Let $\mathcal{T}^n A$ denote the n th iterate of Euclidean threshold growth dynamics with neighbor set $\mathcal{N}$ and threshold θ , started from A . With w defined by (1.11), assume there is a direction $u \in \mathcal{S}^{d-1}$ such that

$$(1.16) \quad w|_{H_u^- \cap \mathcal{S}^{d-1}} > 0.$$

There exists an $m < \infty$ so that if $A \in \mathcal{B}(\mathbb{R}^d)$ is bounded and $B(m) \subset A$, then the dynamics grow linearly with a d -dimensional limiting shape given by the polar transform (1.13)–(1.14) for $1/w$:

$$(1.17) \quad n^{-1} \mathcal{T}^n A \xrightarrow{H} K_{1/w}^*$$

as $n \rightarrow \infty$. Limit law (1.17) also holds if the polar for $1/w$ is completely degenerate, i.e., $K_{1/w}^* = \{\mathbf{0}\}$.

In the Appendix, we show that the half-space condition (1.16) is equivalent to full dimension d (i.e., nonempty interior) for $K_{1/w}^*$. Thus only in *partially degenerate* cases, when the dimension of the polar is less than d but greater than 0, does the shape theorem break down. In some such cases it must be reinterpreted, while others provide genuine counterexamples. Such counterexamples, and the fact that in two dimensions the boundary of L is $\mathcal{C}^1$ only if $K_{1/w}$ is strictly convex, indicate a need for care while fashioning the half-space heuristic into an honest theorem.

To conclude this introduction, let us summarize the organization of the remainder of the paper. For further motivation, §2 presents several concrete examples of Theorem 1. We begin by examining in considerable detail the two-dimensional case where $\mathcal{N}$ is a box of width 2 centered at the origin since, as explained earlier, the resulting limit shapes are related to the behavior of threshold growth cellular automata with large range. The width functions w_θ are computed explicitly and the anisotropy of L_θ is examined as θ varies. None of these shapes is $\mathcal{C}^1$, but for certain values of θ the deviation from a circle is remarkably small. These box neighborhood shapes illustrate certain regularity properties of L that are peculiar to two dimensions. For example, it turns out that L is always “smooth” (i.e., α is $\mathcal{C}^1$) if $\mathcal{N}$ is strictly convex, $\mathcal{N} = -\mathcal{N}$, and $d = 2$; we conjecture that this is not always the case for $d \geq 3$. Also in $d = 2$, if $\mathcal{N}$ is the unit ball of l^p for $p \in [1, \infty]$, then the limit of shapes L_θ as $\theta \rightarrow \frac{1}{2}|\mathcal{N}|$ is the unit ball of the dual space l^q ($\frac{1}{p} + \frac{1}{q} = 1$). This result definitely does not extend to higher dimensions, but was the clue that first led us to understand the role of the polar. As another interesting two-dimensional example, we take $\mathcal{N}$ to be an equilateral triangle region centered at $\mathbf{0}$, in which case $K_{1/w}$ is not convex. The graphs of $K_{1/w}$ and $K_{1/w}^*$ illustrate this counter-intuitive situation. Our final examples deal with degenerate cases when the polar of $1/w$ is nontrivial but the hypothesis of Theorem 1 is not satisfied. Simple two-dimensional neighbor sets show that (i) the limiting shape can depend on the initial configuration, or (ii) the occupied set can grow at a sublinear rate. Also, a prism neighborhood in $\mathbb{R}^3$ shows that growth can remain confined to a bounded region even though $K_{1/w}^*$ is nontrivial, providing a bona fide counterexample to (1.15).

In §3 we use the width function w and monotonicity to show the easy half of the main result in complete generality:

$$(1.18) \quad n^{-1} \mathcal{T}^n A \subset (K_{1/w}^*)^\varepsilon$$

for any bounded $A \subset \mathbb{R}^d$ and all sufficiently large n . One consequence of this upper bound is a trivial limit ($L = \{\mathbf{0}\}$) whenever θ exceeds $\frac{1}{2}|\mathcal{N}|$. The proof of Theorem 1 is completed in §4. Namely, we show that condition (1.16) implies the opposite inclusion

$$(1.19) \quad (n^{-1} \mathcal{T}^n A)^\varepsilon \supset K_{1/w}^*$$

for all sufficiently large n , establishing (1.17) in all but partially degenerate cases. For the sake of clarity, some preliminaries, several properties of the threshold growth transformations $\mathcal{T} = \mathcal{T}_{\theta, \mathcal{N}}$, and a number of standard facts about polar transforms have been relegated to the Appendix. Readers are encouraged to confront these technical details as the need arises and energy permits.

In the final two sections of the paper we return to cellular automata such as (1.1). A limiting shape result is proved for such CA growth rules with arbitrary threshold and range, assuming certain symmetries of the neighbor set N . Since subadditivity is our main tool in the lattice setting we obtain no detailed information about L ; it is simply the unit ball with respect to some implicitly defined norm. Nevertheless, by appealing to the threshold-range scaling that connects lattice transformations T such as (1.6) with a limiting Euclidean transformation $\mathcal{T}$ such as (1.7), we prove that the corresponding implicit asymptotic lattice shapes converge to a shape described by our formula (1.15). For instance, the shape $L_{4/3}$ for the Euclidean box neighborhood that is detailed in the next section provides a very good approximation to the outermost ring generated by the range-10 CA in Figure 2. Both the CA shape result and the threshold-range scaling result are presented in §5 (Theorems 2 and 3, respectively). The paper concludes, in §6, with a brief discussion of excitable cellular automata and their connections to threshold growth dynamics. We define the Greenberg-Hastings and Cyclic CA models that were mentioned earlier and explain why the rings they generate have the same geometry as the shapes generated by our transformations T provided the threshold θ is sufficiently small. However excitable ring dynamics are not monotone, so new and challenging problems arise.

2. EXAMPLES IN TWO AND THREE DIMENSIONS

We will now discuss the asymptotic shape of threshold growth dynamics in six specific settings where $d = 2$ or $d = 3$. Our examples are designed to illustrate (i) explicit quantitative content of the polar formula in concrete cases when $K_{1/w}^*$ is nondegenerate, and (ii) subtleties and counterexamples to the polar formula in some degenerate cases. Example 2 describes two easy corollaries of Theorem 1 that are illustrated by Example 1.

Example 1. Consider the two-dimensional box neighborhood that figured in our introduction: $\mathcal{N} = \{x \in \mathbb{R}^2: \|x\|_\infty \leq 1\}$. Let us compute the width functions w_θ , and graph the limiting shapes L_θ , as θ increases from 0 to $\theta_c = 2$. We parametrize $\mathcal{S}^1$ in terms of the polar coordinate $\varphi \in [0, 2\pi)$. By symmetry, it suffices to compute $w_\theta(\varphi)$ for $0 \leq \varphi \leq \pi/4$. Our undergraduate research

assistant David Perry carried out this rather arduous trigonometric calculation. The result, for $0 < \theta < 2$, is

$$(2.1) \quad w_\theta(\varphi) = \begin{cases} (1 - \frac{\theta}{2}) \cos \varphi & \text{if } \varphi \leq \arctan \frac{\theta}{2}, \\ \cos \varphi + \sin \varphi - \sqrt{\theta \sin 2\varphi} & \text{if } \arctan \frac{\theta}{2} \leq \varphi \leq \frac{\pi}{4}. \end{cases}$$

Note that K_{1/w_θ} has $\mathcal{C}^1$ boundary, but is *not* strictly convex (e.g., near $\varphi = 0$). Thus, by Proposition A2(f) of the Appendix, *none* of the limiting shapes L_θ for the square has a differentiable boundary. As noted in the final paragraph of the Appendix, this is caused by the flat edges of $\mathcal{N}$. In contrast, all the limiting shapes for the neighborhoods $\mathcal{N}_p = \{x \in \mathbb{R}^2: \|x\|_p \leq 1\}$, $1 < p < \infty$, are $\mathcal{C}^1$. That same discussion also implies that *all* shapes $L_{\theta,p}$, $1 \leq p \leq \infty$, are strictly convex.

If K is a two-dimensional bounded convex set, with $\mathcal{C}^1$ boundary represented by $r = r(\varphi)$, and $r^*(\varphi) = \alpha_{K^*}(\varphi)$, then

$$r^*\left(\varphi - \arctan \frac{r'(\varphi)}{r(\varphi)}\right) = \sqrt{\left[\left(\frac{r'(\varphi)}{r(\varphi)}\right)^2 + 1\right]} \cdot \frac{1}{r(\varphi)^2}.$$

Put $r = 1/w$ to get

$$\alpha_L\left(\varphi + \arctan \frac{w'(\varphi)}{w(\varphi)}\right) = \sqrt{w(\varphi)^2 + w'(\varphi)^2}.$$

Plugging in (2.1), we conclude that α_L is given by

$$\alpha_L(\psi(h)) = \sqrt{2 + \frac{\theta}{\sin 2h} - 2\sqrt{\theta} \cdot \frac{\sin h + \cos h}{\sqrt{\sin 2h}}},$$

for $\arctan \frac{\theta}{2} \leq h \leq \frac{\pi}{4}$, where

$$\psi(h) = h - \arctan \left(\frac{\tan h - 1 + \sqrt{\theta} \cdot [(1 - \tan^2 h)/\sqrt{2 \tan h}]}{\tan h + 1 - \sqrt{2\theta \tan h}} \right).$$

Note that $\alpha_{L_\theta}(0) = 1 - \frac{\theta}{2}$, and $\alpha_{L_\theta}(\frac{\pi}{4}) = \sqrt{2} - \sqrt{\theta}$.

In Figure 3 we have plotted L_θ for θ increasing from .1 to 1.9 in increments of .1. Of course the sizes decrease as θ increases. In so doing the shapes interpolate between the square $\mathcal{N}$ and a “diamond.” Notice that for $\theta \approx .3$ the shape is almost circular. In fact, if $B = B_\theta$ denotes the best-fit ball, then at $\theta = .35$ we find that $\sup |\alpha_L(\varphi) - \alpha_B|/\alpha_B < .011$. None of these shapes is precisely a ball since the boundary of each L_θ has discontinuous derivative at $\varphi = 0$. But the fit is sometimes close enough that corresponding lattice cellular automata might appear to generate circular wave fronts. For instance, Greenberg-Hastings rules with fairly small range ρ and threshold θ , where $\theta/\rho^2 \approx .35$ give this (false!) impression. Evidently the issue of isotropic limiting shape is very delicate for lattice growth dynamics. Internal diffusion limited aggregation [9] is one (random) lattice rule that spreads like a Euclidean ball. But despite the claims of some experimentalists, we suspect that in CA models for excitable media the limiting shape of a wave front invariably exhibits residual anisotropy from the underlying lattice.

FIGURE 3

We conclude our discussion of the two-dimensional square neighborhood with a problem for the reader: describe $\lim_{\theta \rightarrow 0} L_{\theta,p}$ for the neighborhoods $\mathcal{N}_{\theta,p}$, $0 < p \leq 1$.

Example 2. Let $\mathcal{N}$ be bounded and convex. Assume that $\alpha_{\mathcal{N}} > 0$ on H_u^- for some $u \in \mathcal{S}$. Then (1.16) holds for all sufficiently small $\theta > 0$; let L_{θ} be the corresponding limit shapes. What is $L_0 = \lim_{\theta \rightarrow 0} L_{\theta}$? If $\theta \approx 0+$, then

$$w(u) \approx S_{\mathcal{N}}(-u) = S_{-\mathcal{N}}(u);$$

hence $1/w \approx \alpha_{-\mathcal{N}^*}$, and so

$$L_{\theta} = K_{1/w}^* \approx -\mathcal{N}^{**} = -\mathcal{N}.$$

(The $\approx$ can be justified using Proposition A2(g).) In fact, it is not hard to see that $L_0 = -\mathcal{N}$ is the limit shape for “ $\theta = 0$ dynamics” $\mathcal{T}_0$ given by

$$\mathcal{T}_0 A = \{x: A \cap (x + \mathcal{N}) \neq \emptyset\} \cup A.$$

This result holds in any dimension. If $\mathcal{N}$ is not convex, but there is a $u \in \mathcal{S}$ such that $|H_v^- \cap \mathcal{N}| > 0$ for all $v \in H_u^-$, then $L_0 = -\text{co}(\mathcal{N})$. L_0 is still the limit shape for $\mathcal{T}_0$ as long as $\mathcal{N}$ contains no sets of measure 0 (e.g., isolated points) that can be separated from the rest of $\mathcal{N}$ by a half-plane. (Such sets play no role in $\mathcal{T}_{\theta}$ for $\theta > 0$, but may clearly influence $\mathcal{T}_0$.)

Under the assumption that $\mathcal{N}$ is *symmetric* (i.e., $-\mathcal{N} = \mathcal{N}$), we will see in §§3 and 4 that L_{θ} is nontrivial for $\theta < \theta_c = \frac{1}{2}|\mathcal{N}|$, and that $\lim_{\theta \uparrow \theta_c} L_{\theta} = \{\mathbf{0}\}$. But what is the limiting *shape* of the set as it shrinks? In the case of Example 1, Figure 3 clearly suggests a diamond. Assume also that $d = 2$ and $\mathcal{N}$ is also $\frac{\pi}{2}$ -rotation symmetric. Then letting $u^{\perp}$ denote the (counter-clockwise) $\frac{\pi}{2}$ -rotation of u , we get

$$\theta_c - \theta \approx 2\alpha_{\mathcal{N}}(u)w(u^{\perp}) = 2\alpha_{\mathcal{N}}(u)w(u).$$

FIGURE 4

Hence

$$\frac{1}{w(u)} \approx \frac{2}{\theta_c - \theta} \alpha_{\mathcal{N}}(u),$$

and so

$$(2.2) \quad \lim_{\theta \uparrow \theta_c} \frac{2}{\theta_c - \theta} L_\theta = \mathcal{N}^*.$$

For instance the limiting shape for the l^p -ball ($1 \leq p \leq \infty$), as $\theta \uparrow \theta_c$, is the l^q -ball ($\frac{1}{p} + \frac{1}{q} = 1$). Evidently, in the general symmetric case (2.2) holds with $\mathcal{N}$ replaced by its $\frac{\pi}{2}$ -rotation. We have checked that this result does *not* extend to $d \geq 3$.

Example 3. Our neighbor set is the two-dimensional triangular region $\mathcal{N} = \text{co}(\{z \in \mathbb{C}: z^3 = 1\})$. Let $\theta = .3$, say. In this case $1/w$ is not convex, so $K_{1/w}$ cannot be approximated by strictly convex sets. But Theorem 1 applies. Figure 4 shows $\mathcal{N}$ (light gray) and a numerical calculation of $K_{1/w}$ (dark gray, not shown on the same scale) and $L = K_{1/w}^*$ (black).

In two dimensions, the *only* situation not covered by Theorem 1 is the *critical case* $\theta = \frac{1}{2}|\mathcal{N}|$. (Our argument for this assertion anticipates results from the next section and the Appendix, so the reader may want to defer study of the remainder of this paragraph.) Proposition 1 in §3 will show that for $\theta > \frac{1}{2}|\mathcal{N}|$, $\mathcal{T}$ is *convex-confined*, meaning that to each bounded set $A \in \mathcal{B}(\mathbb{R}^d)$ there corresponds an $R < \infty$ such that $\mathcal{T}^n A \subset B(R)$ for all $n \geq 0$. If $\mathcal{T}$ is not convex-confined, then (A.6) implies that $\{w = 0\} \subset H_u^-$ for some u . Hence $\{w > 0\} \supset \text{in}(H_u^-) \cap \mathcal{T}$. Choose $u^\perp$ orthogonal to u . As in the proof of Proposition 1, if $\theta < \frac{1}{2}|\mathcal{N}|$ then $w > 0$ either in a neighborhood of $u^\perp$ or a neighborhood of $-u^\perp$. When $d = 2$ (but not for $d > 2$!) this implies that $\{w > 0\} \supset H_{u^\perp}^- \cap \mathcal{T}$ for a suitable choice of sign and small $\delta > 0$. But then hypothesis (1.16) is satisfied. In the critical case, $w(v) > 0$ forces $w(-v) = 0$. So in fact, the only cases in $\mathbb{R}^2$ that are neither convex-confined nor have a

two-dimensional limit shape satisfy

$$(2.3) \quad \theta = \frac{1}{2}|\mathcal{N}|, \text{ and } \{w = 0\} = H_u^- \text{ for some } u.$$

Our next two examples epitomize viable critical growth in the plane. They are prototypes for the two subcases of (2.3): (i) $K_{1/w}^*$ is not completely trivial, and hence is a one-dimensional interval with $\mathbf{0}$ as an endpoint; (ii) $K_{1/w}^*$ is completely trivial even though w is positive on an open half-space. The analysis of Examples 4 and 5 below can be extended to handle (i) and (ii) in general, thereby completing an exhaustive classification of threshold growth dynamics for $d = 2$. We will change notation in Examples 4–6, representing points of $\mathbb{R}^2$ as (x, y) and points of $\mathbb{R}^3$ as (x, y, z) .

Example 4. Let $d = 2$, $\mathcal{N} = B_\infty(1) - e_2$, and $\theta = 2 = \frac{1}{2}|\mathcal{N}|$. Then it is routine to check that $K_{1/w}^* = [0, 1]e_2$. We will show that if $A_m = \{-m \leq x \leq m, -1 \leq y \leq 1\}$ ($m \geq 1$), then

$$(2.4) \quad n^{-1}\mathcal{T}^n A \xrightarrow{H} [0, l_m]e_2$$

for some $l_m < 1$. This is our first counterexample to the polar formula for L . Nevertheless, $l_m \rightarrow 1$ as $m \rightarrow \infty$. In other words, a limit set arbitrary close to $K_{1/w}^*$ can be achieved by starting from a sufficiently large finite set. The arguments for our convergence claims are as follows.

First, to show (2.4), consider the dynamics starting from $A'_m = \{-m \leq x \leq m, y \leq 1\}$. The given $\mathcal{N}$ satisfies (2.3) with $u = e_2$, so growth is only possible in directions v with $\langle v, e_2 \rangle > 0$. For $m \geq 1$, it follows that

$$\begin{aligned} \mathcal{T}^n A_m &= \{-m \leq x \leq m, -1 \leq y \leq g_n(x)\}, \\ \mathcal{T}^n A'_m &= \{-m \leq x \leq m, y \leq g_n(x)\}, \end{aligned}$$

where

$$g_n(x) = \max\{y: (x, y) \in \mathcal{T}^n A'_m\}.$$

Each g_n is a concave real-valued function by Proposition A1(b), and that its maximum occurs at $x = 0$ by symmetry. Also, the “ends” $(m, -1)$ and $(m, 1)$ are pinned, i.e., $g_n(-m) = g_n(m) = 1$ for all n . Introduce the hitting times for $j \geq 0$ given by $t_j = \min\{n \geq 0: g_n(0) \geq j\}$. Consider the evolution of $\mathcal{T}^n A'_m$ until time t_{j+k} . Let us compare with the process obtained by adding extra sites at time t_j to fill $\{-m \leq x \leq m, -\infty \leq y \leq g_{t_j}(0)\}$, and then run until it hits level $j+k$. We conclude that $t_{j+k} \geq t_j + t_k - 1$ ($j, k \geq 0$). Hence the sequence $(t_j - 1; j \geq 0)$ is superadditive, and $\tau = \lim t_j/j = \sup(t_j - 1)/j$ exists. Inverting, and noting that the limit set must be a subinterval of $[0, 1]e_2$, it follows that (2.4) holds with $l_m = \tau^{-1}$.

Next we show that $l_m \rightarrow 1$ as $m \rightarrow \infty$. Thanks to Rick Durrett for suggesting the following construction of a shape that moves up with positive speed. Consider the function $f_m: (-m, m) \rightarrow \mathbb{R}$ given by

$$f_m(x) = -\frac{m^2}{(m-x)(m+x)}.$$

We claim there is an $m_0 < \infty$ such that for $m \geq m_0$ and $0 \leq x_0 \leq x \leq \min\{x_0 + 1, m\}$,

$$(2.5) \quad \max\{f_m(x), f_m(x_0) - 2\} \geq f_m(x_0) + (x - x_0)f'_m(x_0) - \frac{10}{\sqrt{m}}.$$

(One can assume $f_m(x) \geq f_m(x_0) - 2$: otherwise, since $f'_m \leq 0$, for each x_0 the left side is constant while the right side decreases. If $x_0 \leq m - \sqrt{m}$, explicit calculation of the derivative then shows that $\Delta := f_m(x) - f_m(x_0) - (x - x_0)f'_m(x_0) \geq -3/(\sqrt{m} - 1)$, which suffices for large m . If $x_0 \geq m - \sqrt{m}$, then concavity of f_m implies that $x - x_0 \leq -2/f'_m(x_0) \leq 5(m - x_0)^2/m$ (m large). In this case, straightforward estimation yields $\Delta \geq -10(m - x_0)/m \geq -10/\sqrt{m}$ (m large), and the claim follows.) Now consider $\hat{A}_m = \{-m \leq x \leq m, -\infty \leq y \leq f_m(x)\}$. Since $w(v)/\langle v, e_2 \rangle = 1$ for every $v \in \mathcal{S}$ such that $\langle v, e_2 \rangle > 0$, (2.5) implies that for any $\varepsilon > 0$ and m sufficiently large, $n(1-\varepsilon)e_2 + \hat{A}_m \subset \mathcal{T}^n \hat{A}_m$. Hence, by monotonicity, $[0, -1+n(1-\varepsilon)]e_2 \subset \mathcal{T}^n \hat{A}_m$ for all n , so $l_m \geq 1 - \varepsilon$ as desired.

To check that $l_m < 1$ for each m , let $\tilde{A}_m = \{-m \leq x \leq m, y \leq f_{2m}(x)\}$. Using compactness we can find a $\delta > 0$ so that every (x, y) with $x \in [-m, m]$ and $y = f_{2m}(x) + 1$ satisfies $|((x, y) + \mathcal{N}) \cap \tilde{A}_m| < 2 - \delta$. The fact that $f_{2m}(m) = -\frac{4}{3}$, monotonicity, and another application of compactness yield

$$\mathcal{T}^n A'_m \subset \mathcal{T}^n(\frac{7}{3}e_2 + \tilde{A}_m) \subset (n[0, 1 - 2\varepsilon]e_2)^\varepsilon$$

for a suitable choice of $\varepsilon > 0$ and all sufficiently large n .

Example 5. Now take $d = 2$, $\mathcal{N} = ((B(1) + e_1) \cup (B(1) - e_1)) \cap (B_\infty(1) - e_2)$, and $\theta = \frac{\pi}{4} = \frac{1}{2}|\mathcal{N}|$. In this case $L = K_{1/w}^* = \{\mathbf{0}\}$ but if R is sufficiently large and $B(R) \subset A$, then

$$\bigcup_{n \geq 0} \mathcal{T}^n A \text{ is an unbounded set,}$$

i.e., the occupied set exhibits *sublinear growth*. Complete trivality of L follows from Proposition 6 and the fact that

$$\lim_{v \rightarrow e_2} \frac{w(v)}{\langle v, e_2 \rangle} = 0.$$

To establish sublinear growth, introduce the modification $\tilde{\mathcal{T}}$ of $\mathcal{T}$ that maps open sets into open sets:

$$\tilde{\mathcal{T}}A = \{(x, y) : |A \cap ((x, y) + \mathcal{N})| > \theta\} \cup A.$$

Take $A = (-2, 2) \times (-\infty, 1)$. It clearly suffices to show that

$$(2.6) \quad B := \bigcup_{n \geq 0} \tilde{\mathcal{T}}^n A = (-2, 2) \times (-\infty, \infty).$$

If G is any set such that $G - \lambda e_2 \subset G$ for all $\lambda \geq 0$, then $\tilde{\mathcal{T}}G$ has the same property. Hence B also has the same property and there is an upper semicontinuous $f: (-2, 2) \rightarrow (0, \infty]$, symmetric about 0, such that $B = \{(x, y) : -2 < x < 2, y < f(x)\}$. We claim that $f \equiv \infty$.

Assume not. If $f(x) < \infty$, then $|B \cap ((x, f(x)) + \mathcal{N})| \leq \frac{1}{2}|\mathcal{N}|$. Choose $x_k \in (-2, 2)$ so that $x_k \rightarrow x_0$ and $f(x_k) \rightarrow \inf f$. If $x_0 \in (-2, 2)$, then clearly $|B \cap ((x_0, f(x_0)) + \mathcal{N})| > \frac{1}{2}|\mathcal{N}|$. Hence the same must be true for x_k when k is large, a contradiction. We conclude that $\inf f$ is achieved at the two boundary points.

Introduce $g: (-2, 2) \rightarrow (0, \infty]$ defined by $g(x) = \inf\{f(y): y \in [0, x]\}$ for $x \geq 0$, with $g(-x) = g(x)$. Also define g_1 by

$$\widetilde{\mathcal{F}}(\{-2 < x < 2, y < g(x)\}) = \{-2 < x < 2, y < g_1(x)\}.$$

It is easy to see that $g(x) < g_1(x)$ provided $g(x) < \infty$ and

$$(2.7) \quad \liminf_{h \rightarrow 0} \frac{g(x+h) - g(x)}{h} > -\infty.$$

Since $g(2-) < \infty$ and g is nonincreasing in $(0, 2)$, $g(x_0) < g_1(x_0)$ for some $x_0 \in (0, 2)$. However, for each x there are two possibilities: either $f(x) = g(x)$, or there exists an $\varepsilon > 0$ such that $g|_{(x-\varepsilon, x+\varepsilon)} \equiv g(x)$. If x_0 falls in the first category then $f(x_0) < g_1(x_0)$, contradicting the definition of f . Otherwise, replace x_0 by $x'_0 :=$ the left endpoint of the interval containing x_0 on which g is constant. Then $g(x'_0) = f(x'_0)$ and (2.7) must be satisfied at x'_0 . This forces $f(x'_0) = g(x'_0) < g_1(x'_0)$, again a contradiction. Hence $f \equiv \infty$ and (2.6) is proved. In fact, one can show that $\mathcal{F}^n A$ has height of order $\sqrt{n}$ in this example; any other sublinear power law can also be obtained by modifying $\mathcal{N}$ suitably.

Our final example identifies a class of three-dimensional neighbor sets for which critical threshold growth dynamics are convex-confined even though $K_{1/w}^* \neq \{0\}$. This indisputable counterexample to our main formula (1.15) indicates some of the additional complications when $d > 2$.

Example 6. Let $d = 3$. Suppose $\mathcal{N} = (\mathcal{N}' \times [-1, 0])$, where $\mathcal{N}' \in \mathcal{B}(\mathbb{R}^2)$ is a symmetric set with 0 in its interior. If $\theta = \frac{1}{2}|\mathcal{N}'|$, then $K_{1/w}^* = [0, \frac{1}{2}]e_3$, but we claim that $\mathcal{F}$ is convex-confined. The computation of the polar is routine. To show confinement it suffices to let B_R denote an open two-dimensional (circular) disk of radius R centered at the origin, and consider the dynamics starting from $A = B_R \times [0, 1]$, $R < \infty$. The key observation is simple enough: since each half-plane orthogonal to the xy -plane cuts $\mathcal{N}$ in half, there is an $\varepsilon > 0$ such that

$$\mathcal{F}^n A \subset (B_R \times [0, 1]) \cup (B_{R-\varepsilon} \times [1, \infty]) \quad \text{for all } n.$$

Iterating, we get

$$\mathcal{F}^n A \subset \bigcup_{k=0}^{\lfloor R/\varepsilon \rfloor} (B_{R-k\varepsilon} \times [k, k+1]) \quad \text{for all } n.$$

3. THE CASE $\theta > \frac{1}{2}|\mathcal{N}'|$ AND THE UPPER BOUND (1.18)

Let us now begin the proof of Theorem 1. The reader might want to consult the Appendix at this point for a self-contained treatment of the formal set-up, basic notation, and various technicalities. Alternatively, these details can be consulted as they are needed.

To warm up, we first show that for $d \geq 2$, if the threshold exceeds one-half the volume of the neighbor set, then $\mathcal{F}$ is convex-confined: to each bounded set $A \in \mathcal{B}(\mathbb{R}^d)$ there corresponds an $R < \infty$ such that $\mathcal{F}^n A \subset B(R)$ for all $n \geq 0$. Observe the difference from the (asymmetric) one-dimensional case $\theta > \frac{1}{2}|\mathcal{N}|$,

sketched in §1, where (one-sided) growth is possible. Note also that convex-confinement does not say our process *stops* in the sense that $\mathcal{F}^{n+1}A = \mathcal{F}^n A$ for some n , but only asserts that the limit of iterates is bounded.

Proposition 1. *If $\theta > \frac{1}{2}|\mathcal{N}|$, then $\mathcal{F}$ is convex-confined.*

Proof. Fix distinct coordinates $i, j \in \{1, \dots, d\}$, and identify the linear span of $\{e_i, e_j\}$ with $\mathbb{R}^2$. Let P_{ij} be the orthogonal projection of $\mathbb{R}^d$ onto this subspace. For any $u \in \mathcal{S}^{d-1}$, $|\mathcal{N} \cap H_u^-| < \frac{1}{2}|\mathcal{N}|$ iff $|\mathcal{N} \cap H_{-u}^-| > \frac{1}{2}|\mathcal{N}|$. Since the map $\varphi \mapsto |\mathcal{N} \cap H_{(\cos \varphi)e_i + (\sin \varphi)e_j}^-|$ is continuous, we can choose $u \in \mathcal{S}^1 \subset \mathcal{S}^{d-1}$ so that

$$(3.1) \quad |\mathcal{N} \cap H_u^-| = \frac{1}{2}|\mathcal{N}|.$$

By the hypothesis, (3.1) and (1.11), $w(u) = w(-u) = 0$. Continuity also implies that $w = 0$ in a neighborhood of u and $-u$, so we can find $v \neq u$: $w(v) = w(-v) = 0$ as well. Now choose b_{ij}, c_{ij} large enough that

$$A \subset c_{ij} \cdot (H_u^- \cap H_{-u}^- \cap H_v^- \cap H_{-v}^-) \subset \{x \in \mathbb{R}^d : \|P_{ij}x\|_\infty \leq b_{ij}\}.$$

Since each of the half-spaces above has speed 0 and A is enclosed within their intersection, monotonicity of $\mathcal{F}$ implies that $\|P_{ij}(\mathcal{F}^n A)\|_\infty \leq b_{ij}$ for all n . Set $b = \max\{b_{ij}; 1 \leq i, j \leq d\}$ to deduce that $\|\mathcal{F}^n A\|_\infty \leq b$ for all n , proving convex confinement. $\square$

In the preceding proof $1/w = \infty$ on $\{u, -u, v, -v\}$, so property (A.6) shows that $P_{ij}(K_{1/w}^*)$ contains only the two-dimensional origin for each i, j . Hence $K_{1/w}^* = \{\mathbf{0}\}$. Thus the case when $\theta > \frac{1}{2}|\mathcal{N}|$ is completely degenerate, and (1.8) and (1.15) hold starting from any bounded A . Let us now show in full generality that $K_{1/w}^*$ provides an upper bound for the limit set L of Euclidean threshold growth dynamics.

Proposition 2. *Given any $\varepsilon > 0$ and bounded set $A \in \mathcal{B}(\mathbb{R}^d)$, there is an $n_0 < \infty$ such that*

$$n^{-1}\mathcal{F}^n A \subset (K_{1/w}^*)^\varepsilon$$

for all $n \geq n_0$.

Proof. For large $R < \infty$, define approximations to $K_{1/w}$, w , and $K_{1/w}^*$ by

$$M_R = K_{1/w} \cap B(R), \quad w_R = 1/\alpha_{M_R}, \quad L_R = M_R^*,$$

respectively. w is bounded because $\theta > 0$ and $\mathcal{N}$ has finite measure. So M_R is bounded and contains a neighborhood of $\mathbf{0}$. The same holds for L_R by Proposition A2(a)(ii)–(iii). We claim that for each $r > 0$,

$$(3.2) \quad \mathcal{F}(rL_R) \subset (r+1)L_R.$$

To prove (3.2), suppose that α_{L_R} is differentiable in direction $u \in \mathcal{S}$, i.e., $\nu(u) = \nu_{L_R}(u)$ exists. Then monotonicity of $\mathcal{F}$, (1.11), and the fact that $w \leq w_R$ give

$$\begin{aligned} \mathcal{F}(rL_R) &\subset \mathcal{F}(r\alpha_{L_R}(u) \cdot u + H_{\nu(u)}^-) \\ &= r\alpha_{L_R}(u) \cdot u + w(\nu(u)) \cdot \nu(u) + H_{\nu(u)}^- \\ &\subset r\alpha_{L_R}(u) \cdot u + w_R(\nu(u)) \cdot \nu(u) + H_{\nu(u)}^-. \end{aligned}$$

The extent of the last set in direction u is

$$r\alpha_{L_R}(u) + \frac{w_R(\nu(u))}{\langle \nu(u), u \rangle} = (r+1)\alpha_{L_R}(u).$$

Differentiable directions u are dense in $\mathcal{S}$ by Proposition A2(e), so (3.2) follows.

Proposition A2(g)(i) implies that $L_R \xrightarrow{H} K_{1/w}^*$, so choose R large enough that $L_R \subset (K_{1/w}^*)^{\varepsilon/2}$. Then, using the fact that L_R contains a neighborhood of 0 and is bounded, choose r large enough that $A \subset rL_R$ and $L_R \subset r \cdot \frac{\varepsilon}{2} \cdot B(1)$. For $n \geq r^2$, applying (3.2) one gets

$$\begin{aligned} n^{-1}\mathcal{I}^n A &\subset n^{-1}\mathcal{I}^n(rL_R) \subset \frac{n+r}{n}L_R \\ &\subset L_R + \frac{\varepsilon}{2} \cdot B(1) \subset (K_{1/w}^*)^{\varepsilon/2} + \frac{\varepsilon}{2} \cdot B(1) = (K_{1/w}^*)^{\varepsilon}, \end{aligned}$$

as desired. $\square$

4. THE MAIN RESULT: LOWER BOUND (1.19)

In this section we derive lower bound (1.19) for $\mathcal{I}$ under nondegeneracy assumption (1.16); in light of Proposition 2 this will complete the proof of Theorem 1. Our proof of the lower bound constitutes the major technical effort of the paper; it will be broken up into a series of lemmas. The first step expresses a simple idea that was mentioned in the Introduction: given any convex neighborhood A of the origin, with smooth boundary in a vicinity of the direction $u \in \mathcal{S}$, the boundary of a sufficiently large multiple of A is *locally flat* in direction u . Roughly, this means that a sizable chunk of the half-space $(r-\varepsilon)\alpha_A(u) \cdot u + H_{\nu_A(u)}^-$ remains within rA . The precise formulation of the approximation lemma we need is as follows. Figure 5 is intended to help explain the gist of displays (4.1)–(4.3).

FIGURE 5

Lemma 1. Assume that $A \subset \mathbb{R}^d$ is a bounded convex set with $\mathbf{0}$ in its interior, and that α_A is $\mathcal{C}^1$ on an open set $\mathcal{S}_{\text{op}} \subset \mathcal{S} = \mathcal{S}^{d-1}$. Let $\mathcal{S}_{\text{cl}}$ be a closed subset of $\mathcal{S}_{\text{op}}$. Then for every $\varepsilon > 0$ and $c < \infty$, there exists an $r_0 < \infty$ such that for every $r \geq r_0$ and every $u \in \mathcal{S}_{\text{cl}}$,

$$(4.1) \quad ((r - \varepsilon)\alpha_A(u) \cdot u + H_{\nu_A(u)}^-) \cap B(r\alpha_A(u) \cdot u, c) \subset rA \cap B(r\alpha_A(u) \cdot u, c).$$

Proof. We need to check that whenever v satisfies

$$(4.2) \quad \|r\alpha_A(v)v - r\alpha_A(u)u\| \leq c,$$

it follows that

$$(4.3) \quad (r - \varepsilon)\alpha_A(u) \frac{\langle u, \nu_A(u) \rangle}{\langle v, \nu_A(u) \rangle} \leq r\alpha_A(v).$$

By the triangle inequality and (4.2),

$$r\alpha_A(v)\|v - u\| \leq c + r|\alpha_A(v) - \alpha_A(u)|.$$

Also

$$\begin{aligned} \left(\frac{c}{r}\right)^2 &\geq \|\alpha_A(v)v - \alpha_A(u)u\|^2 = (\alpha_A(v) - \alpha_A(u))^2 + 2\alpha_A(u)\alpha_A(v)(1 - \langle u, v \rangle) \\ &\geq (\alpha_A(v) - \alpha_A(u))^2. \end{aligned}$$

Combine the last two inequalities to see that

$$\|v - u\| \leq \frac{2c}{r \min\{\alpha_A(u)\}} = \frac{\bar{c}}{r}.$$

Since α_A is $\mathcal{C}^1$ on $\mathcal{S}_{\text{op}}$, for $u, v \in \mathcal{S}_{\text{cl}}$ we have

$$\alpha_A(v) = \alpha_A(u) \left(1 - \frac{\langle v - u, \nu_A(u) \rangle}{\langle v, \nu_A(u) \rangle} \right) + o(\|v - u\|).$$

Given $\delta > 0$, choose $r_0 = r_0(\delta)$ large enough that the o term in this Taylor expansion is at most $\delta\|v - u\|$ when (4.2) holds, and $r \geq r_0$. Now (4.3) follows provided that

$$\delta \leq \frac{\alpha_A(u)}{\bar{c}} \frac{\langle u, \nu_A(u) \rangle}{\langle v, \nu_A(u) \rangle} \varepsilon.$$

The numerators on the right are bounded below and the denominators are bounded above, so one can select a suitable $\delta = \delta(\varepsilon)$. $\square$

Lower bound (1.19) is easiest to verify when $\mathcal{N}$ is bounded and half-planes propagate in all directions. Our strategy is to find a good smooth approximation L_R to $K_{1/w}^*$ from the *inside*, and then show that a sufficiently large multiple rL_R stays close to $rK_{1/w}^*$ as transformation $\mathcal{T}$ is applied repeatedly. For the sake of clarity, we prove this special case of Theorem 1 before proceeding to consider the general situation.

Lemma 2. Conclusion (1.17) of Theorem 1 holds provided that $\mathcal{N}$ is bounded and $w > 0$.

Proof. For a given large $R < \infty$, define approximations to $K_{1/w}$, w , and $K_{1/w}^*$ by

$$M_R = \bigcap \{B(x, R) : K_{1/w} \subset B(x, R)\}, \quad w_R = 1/\alpha_{M_R}, \quad L_R = M_R^*,$$

respectively. It is not hard to check that M_R is closed and strictly convex. Also, $w_R \leq w$, and M_R converges to $\overline{co}(K_{1/w})$ as $R \rightarrow \infty$. Hence, given $\varepsilon \in (0, 1)$, by Proposition A2(g)(ii) we can choose R so that

$$(4.4) \quad (1 - \varepsilon)K_{1/w}^* \subset L_R.$$

If A is star-shaped with $\mathcal{C}^1$ boundary, define auxiliary transformations $\mathcal{T}_R$ by

$$\alpha_{\mathcal{T}_R(A)}(u) = \alpha_A(u) + \frac{w_R(\nu_A(u))}{\langle u, \nu_A(u) \rangle}.$$

(Roughly, $\mathcal{T}_R$ acts like $\mathcal{T}$ but uses w_R instead of w and pretends that A has flat boundary in the direction of each u .) By (A.4) and the fact that $M_R = L_R^*$,

$$(4.5) \quad \mathcal{T}_R(rL_R) = (r + 1)L_R.$$

Choose $c < \infty$ so that $\mathcal{N} \subset B(c)$, and then apply Lemma 1 to pick r_0 large enough that (4.1) holds for $A = rL_R$, $r \geq r_0$. Under $\mathcal{T}$, sites outside A in direction u encounter an occupied set that effectively covers $(r - \varepsilon)\alpha_A(u) \cdot u + H_{\nu_A(u)}^-$. Thus $\mathcal{T}$ extends A in direction u to at least

$$\left((r - \varepsilon)\alpha_A(u) + \frac{w(\nu_A(u))}{\langle u, \nu_A(u) \rangle} \right) \cdot u.$$

Since $w_R \leq w$, it follows that for $r \geq r_0$,

$$(4.6) \quad \mathcal{T}_R((r - \varepsilon)L_R) \subset \mathcal{T}(rL_R).$$

Iterating (4.5) and (4.6), if $n \geq 1$ then

$$(4.7) \quad (r_0 + (1 - \varepsilon)n)L_R \subset \mathcal{T}^n(r_0L_R).$$

Large balls are locally flat so for sufficiently large m , $B(m + \frac{1}{2} \min w) \subset \mathcal{T}B(m)$. Hence if A contains a large ball $B(m)$, there exists a finite n_0 such that $r_0L_R \subset \mathcal{T}^{n_0}A$. For each $n \geq n_0/\varepsilon$, monotonicity of $\mathcal{T}$, (4.7) and (4.4) yield

$$\begin{aligned} \mathcal{T}^n A &\supset \mathcal{T}^{n-n_0}(r_0L_R) \supset (1 - \varepsilon)(n - n_0)L_R \\ &\supset (1 - \varepsilon)^2(n - n_0)K_{1/w}^* \supset n(1 - 3\varepsilon)K_{1/w}^*. \end{aligned}$$

Divide by n to complete the proof of (1.19) and the lemma. $\square$

Note that we have now established the limiting shape formula (1.15) whenever $\mathcal{N}$ is symmetric (i.e., $-\mathcal{N} = \mathcal{N}$): if $\theta < \frac{1}{2}|\mathcal{N}|$ then $w > 0$ and Lemma 2 applies, whereas if $\theta \geq \frac{1}{2}|\mathcal{N}|$ then $w \equiv 0$ and $\mathcal{T}$ is convex-confined. The next step in our demonstration of Theorem 1 is to assume that w is not strictly positive, but that (1.16) holds for some u . Without loss of generality, assume $u = -e_1$. A new construction of the inner R -approximants M_R , w_R , and L_R is needed to handle this case.

Lemma 3. *Conclusion (1.17) of Theorem 1 holds provided $\mathcal{N}$ is bounded, $w > 0$ on $H_{-e_1}^- \cap \mathcal{S}$, and $w(u) = 0$ for some $u \in H_{e_1}^- \cap \mathcal{S}$.*

Proof. Fix a large $R > 0$ and define the set W_R by its boundary function

$$\alpha_{W_R}(u) = \begin{cases} \infty & \text{if } \|v - u\| < 1/R \text{ for some } v \text{ such that } w(v) = 0, \\ 1/w(u) & \text{otherwise.} \end{cases}$$

Also, for $0 < b < 1$, write

$$g_b(x) = \begin{cases} \sqrt{1-x^2}, & x \in [-b, b], \\ \frac{1-b|x|}{\sqrt{1-b^2}} - \frac{1}{R^2} \frac{(|x|-b)^2}{|x|-b+1} & \text{otherwise.} \end{cases}$$

Note that $g_b: \mathbb{R} \rightarrow (-\infty, 1]$ is strictly convex. Hence the sets

$$G_{R,b} = \left\{ x \in \mathbb{R}^d : x_1 \leq R g_b \left(\frac{1}{R} \sqrt{x_2^2 + \cdots + x_d^2} \right) \right\}$$

are also strictly convex. Let $b > 0$ be any number such that $W_R \subset R e_1 + G_{R,b}$; hypothesis (1.16) guarantees the existence of such a b . An R -approximating region is any set of the form $D = x + U G_{R,b}$, where $x \in B(R)$, U is an orthogonal linear map, and $W_R \subset D$. Now define

$$M_R = \bigcap \{ D : D \text{ is an } R\text{-approximating region} \}.$$

Then M_R is strictly convex, and $M_R \downarrow \overline{\text{co}}(K_{1/w})$ as $R \rightarrow \infty$. As in the previous lemma, let $w_R = 1/\alpha_{M_R}$ and $L_R = M_R^*$. Also, if f is a nonnegative $\mathcal{C}^1$ function defined on $\text{in}(\{u: \alpha_{L_R}(u) > 0\})$, set f equal to 0 elsewhere, and define the auxiliary transformation $\mathcal{T}_R$ by

$$\alpha_{\mathcal{T}_R(K_f)}(u) = \begin{cases} f(u) + \frac{w_R(\nu_{K_f}(u))}{\langle u, \nu_{K_f}(u) \rangle}, & f(u) > 0, \\ 0, & f(u) = 0. \end{cases}$$

Again, for any $r > 0$, $\mathcal{T}_R(rL_R) = (r+1)L_R$. By Proposition A2(g)(ii), $L_R \xrightarrow{H} K_{1/w}^*$; choose R large enough that $(1-\varepsilon)K_{1/w} \subset L_R$. Also, by strict convexity of L_R , if we fix $a > 0$ so that $ae_1 \in \text{in}(L_R)$, then Proposition A2(f)(iii) implies that $\alpha_{L_R-ae_1}$ is $\mathcal{C}^1$ on $\mathcal{S} \setminus \{-e_1\}$. Applying Lemma 1 to $r(L_R - \varepsilon ae_1)$, we can find an r_0 so that for $r \geq r_0$,

$$\begin{aligned} \mathcal{T}(rL_R) &= rae_1 + \mathcal{T}(r(L_R - ae_1)) \\ (4.8) \quad &\supset rae_1 + \mathcal{T}_R((r-\varepsilon)(L_R - ae_1)) \\ &= \varepsilon ae_1 + (r+1-\varepsilon)L_R. \end{aligned}$$

At first glance, (4.8) would appear to finish the proof. We have shown that starting from $A = r_0 L_R$, with R sufficiently large, the limit set for iterates of $\mathcal{T}$ is close to $L = K_{1/w}^*$. But so far there is the possibility that larger and larger A might be required for the dynamics to approach L , i.e., that r_0 might grow with R . To rule out this scenario we appeal to the following fact.

Claim. Let $\mathcal{S}_c$ be a closed subset of $\text{in}(\mathcal{S} \cap H_{-e_1}^-)$ such that $\text{in}(\mathcal{S}_c) \neq \emptyset$, and $K = [0, \infty) \cdot \mathcal{S}_c \subset \mathbb{R}^d$ is convex. Assume also that $\eta = \inf\{w(v) : v \in \mathcal{S} \text{ and } \langle u, v \rangle = 0 \text{ for some } u \in \mathcal{S}_c\} > 0$. Then there is a bounded set $A_0 \in \mathcal{B}(\mathbb{R}^d)$ such that the iterates of $\mathcal{T}$ starting from A_0 eventually cover any bounded Borel set $B \subset K$ (i.e., $B \subset \mathcal{T}^{n_0} A_0$ for some $n_0 < \infty$).

Proof of the claim. It suffices to show the existence of a set A_0 and number k so that $\mathcal{T}^n A_0$ eventually covers any compact subset of $ke_1 + K$. The argument leading to (4.8) produces an A_0 and a convex closed set $\mathcal{S}' \subset \mathcal{S}_c$ such that $\mathcal{T}^n A_0$ eventually covers every compact subset of $K' = [0, \infty) \cdot \mathcal{S}'$. We will prove that the same A_0 satisfies the claim.

In order to apply Lemmas 1 and 2, let us rephrase the problem slightly. Identify $\mathbb{R}^{d-1}$ with $\{x_1 = 0\}$, and define $V \subset \mathbb{R}^{d-1}$ by $e_1 + V = [0, \infty)\mathcal{S}_c \cap (e_1 + \{x_1 = 0\})$. So $[0, \infty)\mathcal{S}_c = [0, \infty)(e_1 + V)$. Define V' analogously in terms of $\mathcal{S}'$. Let $\eta' > 0$ be the minimal length of all projections from any $w(v)v$ to $\{x_1 = 0\}$:

$$\eta' = \min\{w(v)\sqrt{\|v\|^2 - \langle v, e_1 \rangle^2} : v \in \mathcal{S} \text{ and } \langle u, v \rangle = 0 \text{ for some } u \in \mathcal{S}\}.$$

Now let W be any compact subset of V with nonempty interior and $\mathcal{E}^1$ boundary. Lemma 1 says the boundary of rW is nearly flat for $r \geq r_0$, and so $\mathcal{T}([0, \infty)(e_1 + W)) \supset [r, \infty)(e_1 + (1 + \frac{1}{2}\eta')W)$. Choose m large enough that $\mathcal{N} \subset B(m/2)$. It follows that $\mathcal{T}^n([0, \infty)(e_1 + W))$ covers $[r + (n-1)m, \infty)(e_1 + (1 + \frac{n}{2}\eta')W)$. Hence there is a small $\delta > 0$ and a large $k_0 < \infty$ such that $\mathcal{T}^n([0, \infty)(e_1 + W))$ eventually covers every compact subset of $k_0 e_1 + [0, \infty)(e_1 + (1 + 2\delta)W)$. Note that δ depends only on m and η' , but not on W . (On the other hand, k_0 does depend on W .)

If W is convex but not differentiable, use the recipe of Lemma 2 to find a $\mathcal{E}^1$ convex $W \supset W' \supset (1 - \delta)W$. The discussion of the last paragraph thereby produces a large $k_1 < \infty$ such that every compact subset of $k_1 e_1 + [0, \infty)(e_1 + (1 + \delta)W)$ is eventually included in $\mathcal{T}^n([0, \infty)(e_1 + W))$.

The final step in justifying our claim is to apply what we have just proved consecutively to V' , $(1 + \delta)V' \cap V$, $(1 + 2\delta)V' \cap V$, $\dots$, noting that these sets reach V in a finite number of steps. $\square$

To complete the proof of Lemma 3, note that any closed subset of $\text{in}(\{u: \alpha_{L_R}(u) > 0\})$ satisfies the hypotheses of the claim by Proposition A2(b). Let A be any initial set that includes A_0 of the claim. For the chosen R and r_0 in (4.8), select n_0 large enough that $r_0 L_R \subset \mathcal{T}^{n_0} A$. Then for $n > n_0/\varepsilon$,

$$\begin{aligned} \mathcal{T}^n A &\supset \mathcal{T}^{n-n_0}(r_0 L_R) \supset (n - n_0)\varepsilon a e_1 + (1 - \varepsilon)(n - n_0)L_R \\ &\supset (n - n_0)\varepsilon a e_1 + (1 - \varepsilon)^2(n - n_0)K_{1/w}^* \\ &\supset n \left[\left(1 - \frac{n_0}{n}\right) \varepsilon a e_1 + (1 - 3\varepsilon)K_{1/w}^* \right], \end{aligned}$$

and (1.17) follows. $\square$

Finally, to finish the proof of Theorem 1, we remove the assumption that $\mathcal{N}$ is bounded.

Lemma 4. *If (1.17) holds whenever $\mathcal{N}$ is bounded, then it holds for any $\mathcal{N}$ with finite volume.*

Proof. The upper bound (1.18) holds for any $\mathcal{N}$ with finite volume since boundedness was not assumed in Proposition 2. To derive the lower bound (1.19), define $\mathcal{N}_k = \mathcal{N} \cap B(k)$ and let w_k be the corresponding width function. Since $w_k \uparrow w < \infty$ as $k \rightarrow \infty$, and assumption (1.16) holds for w , it also holds for w_k once k is sufficiently large. Thus Lemma 3 applies to each $\mathcal{N}_k$, and so four facts from Proposition A2 yield the desired inclusion (1.19). First, by (g)(iii), $\overline{\text{co}}(K_{1/w_k}) \downarrow \overline{\text{co}}(K_{1/w})$ as $k \rightarrow \infty$. Then (a) parts (i) and (iii) imply that $K_{1/w_k}^* = \overline{\text{co}}(K_{1/w_k})^*$ and $K_{1/w}^* = \overline{\text{co}}(K_{1/w})^*$. Finally, applying (g)(ii), $(n^{-1}\mathcal{T}^n A)^e \supset K_{1/w}^*$ eventually in n . $\square$

Our limit theorem does not apply if the polar of $1/w$ has a positive dimension less than d . We do not know *any* such cases for which the iterates of $\mathcal{F}$ fail to have a limiting shape or the limiting shape is not convex. Recall, however, Examples 4 and 6 from §2: they show that the shape of L need not agree with $K_{1/w}^*$ in these partially degenerate cases.

5. LATTICE THRESHOLD GROWTH DYNAMICS AND THE THRESHOLD-RANGE SCALING LIMIT

Let us now return to cellular automaton rules of the form (1.6) and develop their connection with the limiting shapes L of Theorem 1. The first order of business is a corresponding shape result on $\mathbb{Z}^d$. In contrast to the Euclidean setting, it seems cumbersome to obtain an explicit formula for L on the lattice. Instead, our next theorem exploits subadditivity to establish an implicit characterization.

We introduce two rather ad hoc notions that incorporate technical requirements for our results on the lattice $\mathbb{Z}^d$. Say that $A \subset \mathbb{Z}^d$ is *completely symmetric* if it is invariant with respect to switching sign of the i th coordinate and transposing the i th and j th coordinates ($i, j = 1, \dots, d$). Call $A \subset \mathbb{Z}^d$ *obese* if A is completely symmetric and the following two-part “cone condition” holds:

- (i) If $x \in A$ and $x_1 > 0$, then $x - e_1 \in A$,
- (ii) If $x \in A$ and $x_1 > x_2 > 0$, then $x - e_1 + e_2 \in A$.

Theorem 2. Assume that $N \subset \mathbb{Z}^d$ is obese, and A is a finite set such that $T^n A \uparrow \mathbb{Z}^d$. Then as $n \rightarrow \infty$,

$$n^{-1} T^n A \xrightarrow{H} L = L(N, \theta) \subset \mathbb{R}^d,$$

and L is convex.

Proof. First pick m , R , and n_0 large enough that $N \subset B_1(m)$, $B = B_\infty(R) \supset A$, and $T^n B \supset B_\infty(R)$. For each $x \in \mathbb{R}^d$ define

$$t_x = \min\{n \geq 0: a + B \subset T^n B \text{ for every } a \in B_\infty(x, 1) \cap \mathbb{Z}^d\}.$$

Fix $x, y \in \mathbb{R}^d$, and assume there is a $c \in \mathbb{Z}^d$ such that $\|c - (x + y)\|_\infty \leq 1$. Then there exist sites $a, b \in \mathbb{Z}^d$ such that $\|a - x\|_\infty \leq 1$, $\|b - y\|_\infty \leq 1$, and $c = a + b$. (This is easy to check for $d = 1$, and the general case follows immediately.) As a consequence of this fact and monotonicity of T , the t_x are subadditive, i.e., $t_{x+y} \leq t_x + t_y$ for all $x, y \in \mathbb{R}^d$. Consequently

$$(5.2) \quad \tau(x) := \inf_{n \geq 1} \frac{t_{nx}}{n} = \lim_{n \rightarrow \infty} \frac{t_{nx}}{n}.$$

Using the a priori bounds

$$\frac{\|x\|_1}{m} \leq t_x \leq n_0 \|x\|_\infty,$$

for real λ , with $n = \lfloor \lambda \rfloor$, we have

$$\left| \frac{t_{\lambda x}}{\lambda} - \frac{t_{nx}}{n} \right| \leq \frac{2n_0 \|x\|_\infty}{n}.$$

Hence the limit in (5.2) extends to reals $\lambda \rightarrow \infty$, and $0 < \tau(x) < \infty$ for every $x \neq \mathbf{0}$.

Now define $L = \{\tau \leq 1\}$. Since τ is a norm, L is a closed convex bounded neighborhood of $\mathbf{0}$. Pick $\varepsilon > 0$; to obtain our shape result we need to show that

$$(5.3) \quad (1 - \varepsilon)L \subset n^{-1}(T^n B + B_\infty(\tfrac{1}{2})) \subset (1 + \varepsilon)L$$

once n is sufficiently large. For the left-hand inclusion, if $\tau(x) \leq 1 - \varepsilon$ then $t_{nx} < n$ eventually in n , implying that $nx \in T^n B + B_\infty(\tfrac{1}{2})$. For the right-hand inclusion we need to use the fact that $T^n B$ is obese, by Proposition A1(c). If an obese set F is sufficiently large, then $z + B \subset T^{n_0} F$ whenever $y \in F$ and $z \in B_\infty(y, 1)$. So $nx \in T^n B$ implies that $t_{nx} \leq n + n_0$, and hence $\tau(x) \leq 1 + n_0/n$. Therefore $x \in (1 + \varepsilon)L$ as soon as $n\varepsilon \geq n_0$, (5.3) holds, and Theorem 2 is proved for B instead of A . The final step should be familiar by now: since $T^n A \uparrow \mathbb{Z}^d$ by hypothesis, $B \subset T^{n_1} A$ for some n_1 . Hence

$$T^{n-n_1} B \subset T^n A \subset T^n B$$

for $n \geq n_1$. Divide by n , then send $n \rightarrow \infty$ to complete the proof. $\square$

The reader may well ask how one checks whether any given threshold growth rule $T_{\theta, N}$ admits initial A that eventually cover the entire lattice. For obese neighbor sets N our next proposition states that if the threshold θ is small enough in comparison with $\#N$, then large A satisfying the hypothesis of Theorem 1 always exist. For example this result applies to the range 10 CA discussed in the Introduction, so we have established the limit shape L suggested by Figure 2. We also present a lattice counterpart to Proposition 1, stating that the iterates of any A under $T_{\theta, N}$ eventually stop if N is obese and θ is large compared to $\#N$. Lattice complications preclude an exact evaluation of the cutoff, but as expected it occurs at $\theta \approx \frac{1}{2} \#N$ when N is large.

Proposition 2. *Let N be obese.*

- (a) *If $\theta \leq \frac{1}{2}[\#N - (1 + 2\sqrt{d})\#(N \cap \{x_1 = 0\})]$, then there is a finite $A \subset \mathbb{Z}^d$ such that $T^n A \uparrow \mathbb{Z}^d$.*
- (b) *If $\theta > \frac{1}{2}(\#N - 1)$, then for each finite $A \subset \mathbb{Z}^d$ there exists an n such that $T^{n+1} A = T^n A$.*

Proof. Our argument generalizes one from the Appendix of [6]. Fix a site x in the “lattice ring” $(B(R+1) \setminus B(R)) \cap \mathbb{Z}^d$. Both (a) and (b) are immediate once we show that for large enough R ,

$$(5.4) \quad \tfrac{1}{2}[\#N - (1 + 2\sqrt{d})\#(N \cap \{x_1 = 0\})] \leq \#(B(R) \cap (x + N)) \leq \tfrac{1}{2}(\#N - 1).$$

Now if $y \in B(R) \cap (x + N)$, then $y = x + z$ for some $z \in N$, and hence

$$\|y\|^2 - \|x\|^2 = 2\langle x, z \rangle + \|z\|^2.$$

Thus, if $y \in B(R)$ then $\langle x, z \rangle < 0$. By symmetry, $2\#\{z \in N: \langle x, z \rangle < 0\} + 1 \leq \#N$, and the upper bound in (5.4) follows. On the other hand, $y \in B(R)$ provided that the following two conditions are satisfied for some $\varepsilon > 0$:

$$\langle x, z \rangle \leq -(1 + \varepsilon)R, \quad \text{and} \quad \|z\|^2 \leq 2\varepsilon R - 1.$$

Note that once ε is chosen, the first inequality holds for all z if we take R sufficiently large. Dividing the second inequality by $\|x\|$, it therefore suffices to produce a lower bound on

$$c = \inf_{u \in \mathcal{S}} \#\{z \in N : \langle u, z \rangle \leq -(1 + \varepsilon)\}.$$

Fix $u \in \mathcal{S}$. Then $\langle u, e_i \rangle \geq 1/\sqrt{d}$ for some i ; without loss of generality assume $i = 1$. For every $w \in \mathbb{Z}^{d-1} \cap \{x_1 = 0\}$, the one-dimensional lattice slice $w + \mathbb{Z}e_1$ intersects the set

$$(5.5) \quad \#\{x \in \mathbb{R}^d : -(1 + \varepsilon) \leq \langle u, x \rangle \leq (1 + \varepsilon)\}$$

in at most $1 + 2\sqrt{d}$ points provided $\varepsilon < 1/2\sqrt{d}$. Now use obesity of N to conclude that the cardinality of the intersection of set (5.5) with N is at most $(1 + 2\sqrt{d})\#(N \cap \{x_1 = 0\})$. Therefore

$$2c + (1 + 2\sqrt{d})\#(N \cap \{x_1 = 0\}) \geq \#N,$$

which completes the proof. $\square$

As mentioned in our Introduction, the limit shape L_{10} for the $\rho = 10$, $\theta = 147$ CA of Figure 2 is close to the limit L for Euclidean threshold growth with $\mathcal{N} = B_\infty(1)$ and $\theta = \frac{4}{3}$. Thus the boundary of L_{10} has a shape similar to the 7th smallest ring in Figure 3. Let us now express this connection as a limit theorem for CA dynamics with large range. To do so, we first formalize the notion of lattice transformations T_k converging to a Euclidean transformation $\mathcal{T}$ as $k \rightarrow \infty$.

Definition. A sequence of threshold growth CA rules $T_k = T_{\theta_k, N_k}$, $k \geq 1$, converges to the Euclidean threshold growth rule $\mathcal{T} = \mathcal{T}_{\theta, \mathcal{N}}$ iff

$$\theta_k \rightarrow \infty \quad \text{and} \quad \frac{N_k}{\sqrt{\theta_k}} \xrightarrow{H} \frac{\mathcal{N}}{\sqrt{\theta}} \quad \text{as } k \rightarrow \infty.$$

Theorem 3. Assume that T_k converges to $\mathcal{T}$. Assume further that each N_k is obese, and that $\theta < \frac{1}{2}|\mathcal{N}| < \infty$. Then limiting shapes L_k exist for all sufficiently large k , and

$$\frac{1}{\sqrt{\theta_k}}L_k \xrightarrow{H} \frac{1}{\sqrt{\theta}}L \quad \text{as } k \rightarrow \infty,$$

where $L = L_{\theta, \mathcal{N}}$ is the limiting shape for $\mathcal{T}_{\theta, \mathcal{N}}$.

Proof. Since $\mathcal{T}_{c\theta, c\mathcal{N}}(cA) = c\mathcal{T}_{\theta, \mathcal{N}}A$, $c > 0$, we can assume without loss of generality that $\theta = 1$. Let us start the proof with a few observations. First of all, $\mathcal{N}$ must be obese (the definition for continuous sets being analogous to that in $\mathbb{Z}^d$), and hence star-shaped. Secondly, for fixed $\varepsilon > 0$ and large enough k ,

$$(5.6) \quad (1 - \varepsilon)\mathcal{N} \subset \frac{1}{\sqrt{\theta_k}}(N_k + B_\infty(\tfrac{1}{2})) \subset (1 + \varepsilon)\mathcal{N}.$$

The upper bound in (5.6) follows from the assumed convergence of neighbor sets, the fact that $\mathcal{N}$ is star-shaped and the fact that $\alpha_{\mathcal{N}}$ is bounded below. To verify the lower bound, assume that x is in the leftmost set in (5.6) but not

in the middle set. Let $F \subset \mathbb{R}^d$ denote the set of points with all coordinates nonnegative; we can assume that $x \in F$. Then $x + F$ has empty intersection with the middle set of (5.6) by obesity of N_k . Since $\mathcal{N}$ is obese, there is an $\eta > 0$ and $y \in \mathbb{R}^d$ such that $B(y, \eta) \subset (x + F) \cap \mathcal{N}$. Hence y is at least distance η from $(1/\sqrt{\theta_k})N_k$, a contradiction. Thirdly, as $k \rightarrow \infty$,

$$\#N_k \sim \theta_k |\mathcal{N}|, \quad \text{and} \quad \#(N_k \cap \{x_1 = 0\}) \sim \sqrt{\theta_k} \sigma(\mathcal{N} \cap \{x_1 = 0\}).$$

(σ denotes $d - 1$ dimensional volume.) Lastly, since $|\mathcal{N}| > 2$, Proposition 2 and Theorem 2 imply that L_k exists for large k .

We are now prepared for the heart of the argument. Fix $\varepsilon > 0$. Let $\mathcal{T}' = \mathcal{T}_{1, (1-\varepsilon)\mathcal{N}}$, $\mathcal{T}'' = \mathcal{T}_{1, (1+\varepsilon)\mathcal{N}}$, and also introduce the rescaled lattice dynamics $\mathcal{T}_k$, $k \geq 1$, given by

$$\mathcal{T}_k A = \frac{1}{\sqrt{\theta_k}} (T_k((\sqrt{\theta_k} A) \cap \mathbb{Z}^d) + B_\infty(\tfrac{1}{2})),$$

for each $A \subset \mathbb{R}^d$. Starting from sufficiently large “cubes” $A_k = B_\infty(R_k)$, as $n \rightarrow \infty$ one gets

$$n^{-1} \mathcal{T}_k^n A_k \xrightarrow{H} \mathcal{L}_k = \frac{1}{\sqrt{\theta_k}} L_k.$$

We claim next that if k is large enough and A is of the form $(A^\# + B_\infty(\frac{1}{2}))/\sqrt{\theta_k}$ for some $A^\# \subset \mathbb{Z}^d$, then $\mathcal{T}' A \subset \mathcal{T}_k \subset \mathcal{T}'' A$. Assume first that $x \in \mathcal{T}' A$. Let $x' \in \mathbb{Z}^d$ be such that

$$(5.7) \quad \left\| x - \frac{1}{\sqrt{\theta_k}} x' \right\|_\infty \leq \frac{1}{2\sqrt{\theta_k}}.$$

Then if θ_k is small enough, all cubes

$$(5.8) \quad \frac{1}{\sqrt{\theta_k}} B_\infty(y, \tfrac{1}{2})$$

with $y \in A^\#$ that have nonempty intersection with $x + (1 - \varepsilon)\mathcal{N}$ are completely contained in $(x' + N_k + B_\infty(\frac{1}{2}))/\sqrt{\theta_k}$. The number of such cubes is at least θ_k ; otherwise $|x + (1 - \varepsilon)\mathcal{N} \cap A| < \theta_k^{-1} \theta_k$, a contradiction. Hence $x' \in \mathcal{T}_k A$, and consequently $x \in \mathcal{T}_k A$. Now assume that $x \in \mathcal{T}_k A$. Then there is an $x'' \in \mathbb{Z}^d$ satisfying (5.7) and such that the number of cubes (5.8) with $y \in A^\#$ and completely inside $(x'' + N_k + B_\infty(\frac{1}{2}))/\sqrt{\theta_k}$ is at least θ_k . If k is large enough, then all these cubes are inside $x + (1 + \varepsilon)\mathcal{N}$, so $|(x + (1 + \varepsilon)\mathcal{N}) \cap A| \geq 1$, and hence $x \in \mathcal{T}'' A$.

Passing to the limit, the claim we have just proved yields

$$L_{1, (1-\varepsilon)\mathcal{N}} \subset \mathcal{L}_k \subset L_{1, (1+\varepsilon)\mathcal{N}}.$$

For every bounded Borel $\mathcal{N}$, $\mathcal{N}'$ and A , $\mathcal{T}_{\theta, \mathcal{N}'} A \subset \mathcal{T}_{\theta - |\mathcal{N}' \setminus \mathcal{N}|, \mathcal{N}} A$. To complete the proof of the theorem, it therefore suffices to verify that $L_{\theta, \mathcal{N}}$ converges to $L_{1, \mathcal{N}}$ if θ increases or decreases to 1. But this follows directly from Proposition A2(g). $\square$

Theorem 3 establishes that the asymptotic shape of a threshold growth CA with large range is well approximated by a more explicit Euclidean threshold

growth limit L . In this sense the continuous process is more tractable. Suppose, however, that we want to study detailed aspects of the geometry of $\mathcal{T}^n A$, e.g., boundary behavior or interaction effects between several growing regions. One approach is to visualize the Euclidean dynamics on a computer. Apparently the most natural way to do so is to replace $\mathcal{T}$ by a suitable CA rule T with very large range. This illustrates an illuminating interplay between the discrete and continuous settings.

6. FINAL REMARKS ON THE CONNECTION WITH EXCITABLE MEDIA

Let us conclude by outlining some connections with models for two-dimensional excitable media. As mentioned in the introduction, our computer experiments with Greenberg-Hastings and cyclic cellular CA rules, reported in [6], were the original motivation for the present work. The color graphics of that article show examples of periodic wave generation by spiral cores known as *stable periodic objects*. In many cases the wave fronts evolve as if they were governed by a monotone rule T , and hence are close to a suitable $\mathcal{T}$ once the range is sufficiently large. In such instances a corresponding shape $L = K_{1/w}^*$ gives a good approximation to the geometry of the wave fronts.

To convey the spirit of these remarks more precisely, we introduce a Euclidean *deterministic forest fire* (DFF) on $\mathbb{R}^2$ as follows. At each time n the state of the system consists of two disjoint Borel subsets of $\mathbb{R}^2$: F_n (points “on fire”), and E_n (“burnt” points). The dynamics are

$$F_{n+1} = \{x \in \mathbb{R}^2 \setminus (F_n \cup E_n) : |(F_n \cap (x + \mathcal{N}))| \geq \theta\}, \quad E_{n+1} = F_n \cup E_n.$$

Here θ and $\mathcal{N}$ are the same parameters as for $\mathcal{T}$. In words, a point which is neither on fire nor burnt is ignited next time if the volume of overlap between its neighborhood and the currently burning region exceeds θ , and any point remains ignited for a single time unit before it becomes burnt. Theorem 1 has the following consequence for Euclidean DFF dynamics with small threshold.

Corollary 1. *Let $\mathcal{N}$ be completely symmetric and convex. Assume that $E_0 = \emptyset$ and F_0 is a completely symmetric and convex set that contains $B(R)$ for a suitably large R (e.g., $8\mathcal{N} \subset B(R)$). There exists a $\theta_0 = \theta_0(\mathcal{N}) > 0$ such that if $\theta < \theta_0$, then $n^{-1}E_n \xrightarrow{H} L$ as $n \rightarrow \infty$, where L is the limiting shape for $\mathcal{T} = \mathcal{T}_{\theta, \mathcal{N}}$.*

Proof. We will show that $F_n \cup E_n = \mathcal{T}^n F_0$ for all $n \geq 0$; once this identity is established the corollary is an immediate consequence of Theorem 1. Observe first that, by Proposition A1(b), $\mathcal{T}^n F_0$ is completely symmetric and convex for every n provided that $\widehat{\mathcal{T}}A \supset A$. For the sake of brevity, let us write φ in place of $u_\varphi = \cos \varphi e_1 + \sin \varphi e_2$ ($\varphi \in [0, 2\pi)$). It suffices to verify the following claim for all sufficiently small $\theta > 0$:

If A is a large completely symmetric convex set, and

$$\lambda_\varphi = \sup\{\lambda > 0 : A \cap (\lambda\varphi + \mathcal{N}) \neq \emptyset\},$$

then $\mu_\varphi = |\mathcal{T}A \cap (\lambda_\varphi\varphi + \mathcal{N})| \geq \theta$ ($\varphi \in \mathcal{S}$). Let $a = 2\alpha_{\mathcal{N}}(\pi/8) \sin(\pi/8)$. Introduce the quarter-spaces

$$Q_\varphi^- = \bigcap \{H_\psi^- : \cos(\varphi - \psi) = 1/\sqrt{2}\}, \quad \varphi \in \mathcal{S}.$$

By the assumed properties of A , it suffices to check the claim in two cases. The first is when $A = Q_{\pi/4}^-$ and $\varphi \in [0, \frac{\pi}{2}]$; the second is when $A = Q_0^-$ and $\varphi \in [-\frac{\pi}{4}, \frac{\pi}{4}]$. To handle the first case, let

$$\delta = \min \left\{ \frac{1}{\sqrt{2}} \alpha_{\mathcal{F} Q_{\pi/4}^-} \left(\frac{\pi}{4} \right), \frac{1}{\sqrt{2}} a \right\}.$$

Clearly δ increases with θ and $\delta > 0$ if θ is small enough. But $\mu_\varphi \geq \delta^2$ for every $\varphi \in [0, \frac{\pi}{2}]$. The second case can be dealt with similarly. $\square$

We remark that if $\mathcal{N} = B_\infty(1)$, then the idea of this last argument yields a θ_0 slightly larger than $\frac{1}{4}$. We believe that the result should hold with $\theta_0 = \frac{1}{2}$, but not for larger θ_0 . In order to achieve that improvement one would need to substitute half-spaces for the Q_φ^- . At larger thresholds than $\frac{1}{2}$ the Euclidean DFF dynamics cease to agree with $\mathcal{F}^n$, and entirely new methods are needed for their study.

Similar techniques apply to analogously defined DFF CA rules. Assume for simplicity that $N_k = k\mathcal{N} \cap \mathbb{Z}^2$, where $\mathcal{N}$ is as in Corollary 1. There exists a constant $c = c(\mathcal{N})$ such that if $\theta_k < k^2\theta_0 - ck$, then the following is true. If $F_0 = B_\infty(R) \cap \mathbb{Z}^2$ for a sufficiently large R , and $E_0 = \emptyset$, then $n^{-1}E_n \xrightarrow{H} L$ as $n \rightarrow \infty$, where L is the limiting shape for $T = T_{\theta, N}$. For example, if $\mathcal{N} = B_\infty(1)$, then $\theta_k \leq \frac{1}{4}k^2 - \frac{1}{2}k$ suffices.

Let us now formally define the Greenberg-Hastings model ξ_t (GHM) and cyclic cellular automaton ζ_t (CCA), models for excitable media that were mentioned in the Introduction. These are the iterated transformations on $\{0, 1, \dots, \kappa - 1\}^{\mathbb{Z}^2}$, $\kappa \geq 3$, that were studied in [6]. Starting from ξ_0 and ζ_0 , respectively, the GHM and CCA are defined recursively by

(GH)

$$\begin{aligned} \xi_{t+1}(x) &= (\xi_t(x) + 1) \bmod \kappa && \text{if } \xi_t(x) \geq 1 \quad \text{or} \quad \#\{y \in x + N : \xi_t(y) = 1\} \geq \theta, \\ &= \xi_t(x) && \text{otherwise;} \end{aligned}$$

(CCA)

$$\begin{aligned} \zeta_{t+1}(x) &= (\zeta_t(x) + 1) \bmod \kappa && \text{if } \#\{y \in x + N : \zeta_t(y) = (\zeta_t(x) + 1) \bmod \kappa\} \geq \theta, \\ &= \zeta_t(x) && \text{otherwise.} \end{aligned}$$

The following result for GHM or CCA dynamics started from a lattice ball of 1's on a background of 0's is essentially a restatement of the discrete version of Lemma 1.

Corollary 2. *Assume that N_k is as above and $\theta_k \leq k^2\theta_0 - ck$. Let the initial state have all 1's on $B_\infty(R)$ and 0's elsewhere, where R is large. For either GHM or CCA, let $R_t = \{x : 1 \text{ at } x \text{ at time } t\}$, $S_t = \{x : 1 \text{ at } x \text{ at some time } s \leq t\}$. Then $t^{-1}S_t \rightarrow L$ as $t \rightarrow \infty$, and if κ is sufficiently large then $t^{-1}R_t \rightarrow \alpha_L(\mathcal{F})$ (the boundary of L). Here L is the limit shape of the (θ_k, N_k) threshold growth CA.*

This last result describes “ring dynamics.” In the terminology of [6], for $\mathcal{N} = B_\infty(1)$, it states that $\text{ball}(k) \geq \frac{1}{4}k^2 - \frac{1}{2}k$. However it also accurately describes the shapes of wave fronts that one sees in excitable cellular automata started from random initial states provided θ is sufficiently small. The reason

is better understood for GHM: stable periodic objects form rapidly, and they invariably produce nested rings provided κ is suitably large. These rings must then propagate with the asymptotic shape described in Corollary 2. Spiral formation in CCA rules is less well understood. Suffice it to say that emergent wave fronts with limiting shape L are observed experimentally in both the locally periodic and turbulent regions of the phase diagram (cf. [6]).

In conclusion, we would like to mention one natural extension of our threshold growth dynamics that may find application in more detailed models for excitable media. Namely, more general functionals might replace the neighbor set $\mathcal{N}$ in the sense that $\mathcal{T}A = \widehat{\mathcal{T}}A \cup A$, where

$$\widehat{\mathcal{T}}A = \left\{ x \in \mathbb{R}^d : \int_A f(x+y) dy \geq \theta \right\},$$

i.e., $f = 1_{\mathcal{N}}$ is replaced by any $f: \mathbb{R}^d \rightarrow [0, \infty)$ such that $\int f < \infty$. After extending the definition of the width function w in a straightforward manner, many techniques and results from this paper apply.

APPENDIX: PRELIMINARIES AND TECHNICAL DETAILS

Let us denote the l^p -ball of radius r centered at x by

$$B_p(x, r) = \{y \in \mathbb{R}^d : \|y - x\|_p \leq r\},$$

$1 \leq p \leq \infty$. We will abbreviate $B_p(r) = B_p(\mathbf{0}, r)$, and usually omit the subscript when $p = 2$. To each vector u in the unit sphere $\mathcal{S}$ there corresponds a half space H_u^- defined by (1.10). The standard basis vectors are written as e_i ($1 \leq i \leq d$). The Borel σ -algebra on $\mathbb{R}^d$ is denoted by $\mathcal{B}(\mathbb{R}^d)$, and we write $|A|$ for the Lebesgue measure of a set $A \in \mathcal{B}(\mathbb{R}^d)$. Also, set $\#A$ = the cardinality of set A .

A set $K \subset \mathbb{R}^d$ is called *star-shaped* (with respect to $\mathbf{0}$) if $\{\lambda x : 0 \leq \lambda < 1\} \in K$ whenever $x \in K$. For any $f: \mathcal{S} \rightarrow [0, \infty]$, the shape K_f is given by (1.14) is clearly star-shaped. On the other hand, if $K \subset \mathbb{R}^d$ is any star-shaped set, then its boundary can be represented by a function $\alpha_K: \mathcal{S} \rightarrow [0, \infty]$ defined as

$$(A.1) \quad \alpha_K(u) = \sup\{\lambda \geq 0 : \lambda u \in K\}.$$

Let us now introduce formally the Euclidean and lattice transformations that we will study. Fix *neighbor sets* $\mathcal{N} \in \mathcal{B}(\mathbb{R}^d)$ with finite volume, and finite $N \subset \mathbb{Z}^d$. Also fix a real *threshold* $\theta > 0$. Define $\widehat{\mathcal{T}}: \mathcal{B}(\mathbb{R}^d) \rightarrow 2^{\mathbb{R}^d}$, and $\widehat{\mathcal{T}}: 2^{\mathbb{Z}^d} \rightarrow 2^{\mathbb{Z}^d}$, by

$$\begin{aligned} \widehat{\mathcal{T}}A &= \{x \in \mathbb{R}^d : |(A \cap (x + \mathcal{N}))| \geq \theta\}, \\ \widehat{T}B &= \{x \in \mathbb{Z}^d : \#(B \cap (x + N)) \geq \theta\}, \end{aligned}$$

where $A \in \mathcal{B}(\mathbb{R}^d)$ and $B \subset \mathbb{Z}^d$ are arbitrary. In keeping with (1.6)–(1.7), write

$$\mathcal{T}A = \widehat{\mathcal{T}}A \cup A \quad \text{and} \quad TB = \widehat{T}B \cup B.$$

Our first proposition identifies some basic properties of these mappings. The definition of obesity appears in §5 (cf. (5.1)).

Proposition A1. (a) For any $A \in \mathcal{B}(\mathbb{R}^d)$, $x \mapsto |A \cap (x + \mathcal{N})|$ is a continuous map from $\mathbb{R}^d$ to $\mathbb{R}$. Hence $\widehat{\mathcal{T}}$ and $\mathcal{T}$ map $\mathcal{B}(\mathbb{R}^d)$ into $\mathcal{B}(\mathbb{R}^d)$.

(b) Assume that $\mathcal{N}$ is convex. If $A \subset \mathbb{R}^d$ is convex, then $\widehat{\mathcal{T}}A$ is convex.

(c) Assume that N is obese. If $A \subset \mathbb{Z}^d$ is obese, then so are $\widehat{T}A$ and TA .

Proof. For $\varepsilon > 0$, define $\mathcal{N}^\varepsilon = \mathcal{N} + B(\varepsilon)$, and $\mathcal{N}^{-\varepsilon} = ((\mathcal{N}^c)^\varepsilon)^c$. Then $\mathcal{N}^{-\|x\|} \subset x + \mathcal{N} \subset \mathcal{N}^{\|x\|}$. Thus the map in (a) is continuous at $x = 0$; a translate of $\mathcal{N}$ handles any x .

To prove (b), fix $\lambda \in (0, 1)$ and two vectors $x, y \in \mathbb{R}^d$, and define the functions

$$f = 1_{(x+\mathcal{N}) \cap A}, \quad g = 1_{(y+\mathcal{N}) \cap A}, \quad \text{and} \quad h = 1_{(\lambda x + (1-\lambda)y + \mathcal{N}) \cap A}.$$

By convexity of $\mathcal{N}$ and A , $h(\lambda r + (1-\lambda)s) \geq f(r)^\lambda g(s)^{1-\lambda}$ for each $r, s \in \mathbb{R}^d$. Hence Lemma 1.2 of Pisier [10] yields

$$\int h \geq \left(\int f \right)^\lambda \left(\int g \right)^{1-\lambda}.$$

If both integrals on the right side exceed θ , then the integral on the left does as well, so $\widehat{\mathcal{T}}A$ is convex.

Under the hypotheses of (c), complete symmetry of $\widehat{T}A$ and TA follow from complete symmetry of counting measure on $\mathbb{Z}^d$. Cone condition (5.1(i)) for obesity of $\widehat{T}A$ boils down to

$$(A.2) \quad \#(((x+N) \setminus (x-e_1+N)) \cap A) \leq \#(((x-e_1+N) \setminus (x+N)) \cap A)$$

whenever $x_1 > 0$. Let B and C denote the sets being counted on the left and right sides of (A.2), respectively. We claim that $f(y) = y - 2(y_1 - x_1)e_1 - e_1$ is an injection from B to C . Obesity implies that each slice $\{y \in N : y_2, \dots, y_d \text{ are fixed}\}$ is an interval of integers symmetric about 0. Thus distinct sites in B must differ in some coordinate other than the first, so f is one-one. Now fix $y \in B$. First note that y must satisfy $y_1 \geq x_1 > 0$, since obesity of N and $y_1 < x_1$ yield the string of implications: $y \in x + N \Rightarrow x - y \in N \Rightarrow x - y - e_1 \in N \Rightarrow y \in x - e_1 + N$. Thus $y \in x + N \Rightarrow y - x - 2(y_1 - x_1)e_1 \in N \Rightarrow f(y) \in x - e_1 + N$. Also, $y \notin x - e_1 + N \Rightarrow f(y) \notin x + N$. Finally, obesity of A implies that $y - ce_1 \in A$ for $0 \leq c \leq 2y_1$, and $2(y_1 - x_1) - 1 \leq 2y_1$ since $x_1 \geq 1$. Together these conclusions show that $f(y) \in C$. (A.2) follows. A similar argument verifies (5.1(ii)) for $\widehat{T}A$. Since A and $\widehat{T}A$ are obese, so is TA . (Unions of obese sets are obese.) $\square$

Repeated application of any one of the four transformations introduced above gives rise to a dynamical system; we use a superscript n to denote the n th iterate. Part (a) of Proposition A1 ensures that iteration is well defined in the Euclidean setting. In this paper we focus on $\mathcal{T}^n$; §5 contains results for T^n and a connection between the lattice and Euclidean rules. $\widehat{\mathcal{T}}$ and $\widehat{T}$ are interesting in their own right, but we use them only as auxiliary dynamics in §§4 and 6. Let us note in passing that $\mathcal{T}$ need not preserve convexity when $\mathcal{N}$ is convex; there are easy counterexamples.

As explained in the Introduction, the polar transform (1.13) on sets $K \subset \mathbb{R}^d$ plays a key role in our results. The next order of business is to collect needed

facts about K^* ; most are well known to convex analysts. First, given $K \subset \mathbb{R}^d$, define $S_K: \mathcal{S} \rightarrow [0, \infty)$ by $S_K(u) = \sup\{\langle x, u \rangle : x \in K\}$. Then (1.13) and (A.1) easily imply that

$$(A.3) \quad \alpha_{K^*} = 1/S_K$$

($\frac{1}{0} = \infty, \frac{1}{\infty} = 0$). Assume temporarily that K is compact and convex, with $\mathcal{C}^1$ boundary, and $\mathbf{0} \in K$. Let $\nu_K: \mathcal{S} \rightarrow \mathcal{S}$ denote the (outward) normal bundle of K . Then ν_K is surjective, and $S_K(\nu_K(u)) = \alpha_K(u)\langle u, \nu_K(u) \rangle$ for each $u \in \mathcal{S}$. Hence

$$(A.4) \quad \alpha_{K^*}(\nu_K(u)) = \frac{1}{\alpha_K(u)\langle u, \nu_K(u) \rangle} \quad \text{for each } u \in \mathcal{S}.$$

Comparing (1.12) and (A.5), our heuristic evaluation of the limiting velocities $\alpha_L(u)$ should solve

$$(A.5) \quad w(\nu_L(u)) = 1/\alpha_{L^*}(\nu_L(u)),$$

or equivalently, $\alpha_{L^*} = 1/w$. That is to say, $L^* = K_{1/w}$. As noted below, $K^{**} = K$ for closed convex sets K . Hence, taking the polar of both sides, we get (1.15).

Since our goal is to establish the formula (1.15) even when L is not smooth and $1/w$ is not convex, we need a less restrictive analog of (A.5). This and other fundamental properties of the general polar transform are collected in the next proposition. $\text{cl}(\cdot)$, $\text{in}(\cdot)$, and $\text{co}(\cdot)$ denote the closure, interior, and convex hull of a set, respectively. We abbreviate $\overline{\text{co}}(\cdot) = \text{cl}(\text{co}(\cdot))$.

Proposition A2.

- (a) If K is any subset of $\mathbb{R}^d$, then
 - (i) K^* is a convex set that contains $\mathbf{0}$, and $K^* = \overline{\text{co}}(K)^*$;
 - (ii) K^* contains a neighborhood of $\mathbf{0}$ iff K is bounded;
 - (iii) K^* is bounded iff $\overline{\text{co}}(K)$ contains a neighborhood of $\mathbf{0}$.
- (b) Assume that K is star-shaped and unbounded, and that α_K is continuous on $\{\alpha_K < \infty\}$. Then K^* has nonempty interior iff there is a $u \in \mathcal{S}$ such that $\alpha_K(\cdot) < \infty$ on $H_u^- \cap \mathcal{S}$. If such a u exists,

$$\text{cl}(\{u \in \mathcal{S} : \alpha_{K^*}(u) > 0\}) = \bigcap \{H_u^- : \alpha_K(u) = \infty\} \cap \mathcal{S}.$$
- (c) Assume that K is star-shaped and α_K is $\mathcal{C}^1$. Then (A.4) holds for each $u \in \mathcal{S}$ such that $\alpha_K(u) = \alpha_{\text{co}(K)}$, and $\{\nu_K(u) : \alpha_K(u) = \alpha_{\text{co}(K)}(u)\} = \mathcal{S}$.
- (d) Let K be closed and star-shaped. Then the existence of $\nu_{K^*}(u)$ for some fixed $u \in \mathcal{S}$ implies that $\alpha_K(\nu_{K^*}(u)) \cdot \nu_{K^*}(u)$ is an extreme point of $\text{co}(K)$.
- (e) If K is convex and contains $\mathbf{0}$, then $D = \{u : \nu_K(u) \text{ exists}\}$ is dense in $\mathcal{S}$ and (A.4) holds for $u \in D$.
- (f)
 - (i) If K is closed, convex, and contains $\mathbf{0}$, then $K^{**} = K$;
 - (ii) Let K be a bounded star-shaped neighborhood of $\mathbf{0}$. Then K^* is strictly convex iff α_K is $\mathcal{C}^1$, and K is strictly convex iff α_{K^*} is $\mathcal{C}^1$.
 - (iii) Assume that K is strictly convex, unbounded, and $\alpha_K|_{\mathcal{S} \cap H_u^-} < \infty$ for some $u \in \mathcal{S}$. Then the boundary of K^* is $\mathcal{C}^1$ away from the origin. Equivalently, there is an $a > 0$ such that $au \in \text{in}(K^*)$ and $\alpha_{K^* - au}$ is $\mathcal{C}^1$ on $\mathcal{S} \setminus \{u\}$.

(g) Let $K_m \subset \mathbb{R}^d$; $m \geq 1$.

- (i) If $K_m \uparrow K$, and K^* is bounded, then $K_m^* \downarrow K^*$ and $K_m^* \xrightarrow{H} K^*$;
- (ii) If K_m are closed and convex, $K_m \downarrow K$, and K^* is bounded, then $K_m^* \xrightarrow{H} K^*$.
- (iii) Assume that $f, f_k: \mathcal{S} \rightarrow [0, \infty)$ are continuous, and $f_k \uparrow f$ as $k \rightarrow \infty$. Assume also that $f > 0$ on $H_{-e_1}^- \cap \mathcal{S}$. Then $\overline{\text{co}}(K_{1/f_k}) \downarrow \overline{\text{co}}(K_{1/f})$ as $k \rightarrow \infty$.

Note. In part (g) and henceforth, $K_m \uparrow K$ for subsets of $\mathbb{R}^d$ means that $K_m \subset K_{m+1}$ for each m and that $K = \bigcup_m K_m$. Similarly for $K_m \downarrow K$. This does *not* imply convergence in the Hausdorff metric.

Proof. See Istratescu [4] for (a) part (i), (c), (d) and (f). Roberts and Varberg prove (e) in [11]. Parts (a)(ii)–(iii) and (b) follow easily from (A.3), the fact that

$$(A.6) \quad S_K(v) = \infty \text{ whenever } \alpha_K(u) = \infty \text{ and } \langle u, v \rangle > 0,$$

and the assumed continuity of α .

The assertions of part (g) are not quite as standard, so we will outline their proofs. For (i), first note that if $K_m \uparrow K$, then $K_m^* \downarrow K^*$. Suppose the K_m^* do not converge to K^* in the Hausdorff metric. By (a)(i), K_m^* is convex for each m . Then since K^* is bounded, we can find $\varepsilon > 0$, $R < \infty$ so that $z_m \in (K_m^* \setminus (K^*)^\varepsilon) \cap B(\mathbf{0}, R)$ for all m . Let z be a subsequential limit of the z_m . For each m , $z \in K_m^* \cap B(\mathbf{0}, R)$ (closed), and hence $z \in K^*$. But each z_m is separated from K^* by distance at least ε , a contradiction. This proves part (i). We omit the proof of (ii), which is similar once one applies (f)(i) to see that $(\bigcup K_m^*)^* = K^*$, and hence $\text{cl}(\bigcup K_m^*) = K^*$.

Finally, the more intricate argument for (g)(iii) goes as follows. Note first that the f_k converge uniformly to f because the f_k and f are continuous and the limit is monotone. Hence, for every $\varepsilon > 0$, there exists a $\delta > 0$ and a k_0 so that for $k \geq k_0$,

$$\{f_k \leq \delta\} \subset \{f = 0\}^\varepsilon.$$

After inversion this becomes

$$(A.7) \quad K_{1/f_k} \cap B(1/\delta)^c \subset [0, \infty)\{f = 0\}^\varepsilon.$$

By uniform convergence of $\min\{1/f_k, 1/\delta\}$, we can enlarge k_0 if necessary so that for $k \geq k_0$,

$$(A.8) \quad K_{1/f_k} \cap B(1/\delta) \subset K_{1/f}^\varepsilon.$$

Now (A.7) and (A.8) together imply that

$$(A.9) \quad K_{1/f_k} \subset (\overline{\text{co}}(K_{1/f}) + [0, \infty)\{f = 0\}^\varepsilon)^\varepsilon.$$

In view of (A.9) we need to establish the following

Claim. Let K be any closed convex set including $\mathbf{0}$ such that $\alpha_K < \infty$ on $H_{-e_1}^- \cap \mathcal{S}$. Then for sufficiently small $\varepsilon > 0$,

$$K_\varepsilon = K + [0, \infty)\{\alpha_K = \infty\}^\varepsilon$$

is a closed convex set, and $K_\varepsilon \downarrow K$ as $\varepsilon \downarrow 0$.

Assuming the validity of the claim for a moment, let us see how it completes the proof. Set $K = \overline{\text{co}}(K_{1/f})$. Clearly, by monotonicity, $K \subset \overline{\text{co}}(K_{1/f_k})$ for all k . By (A.9) on the other hand, $K_{1/f_k} \subset K_\varepsilon^\varepsilon$, which is closed and convex since K_ε is closed and convex for small enough ε . Hence $\overline{\text{co}}(K_{1/f_k}) \subset K_\varepsilon^\varepsilon$. Finally, $K_\varepsilon^\varepsilon \downarrow K$ as $\varepsilon \rightarrow 0$, again because the K_ε are closed. Thus $\overline{\text{co}}(K_{1/f_k}) \downarrow K$, as was to be proved.

Now let us verify the claim. First, choose m large enough that $K \cap B(m)^c \subset [0, \infty)\{\alpha_K = 0\}^\varepsilon$. Then $K_\varepsilon = (K \cap B(0, m)) + [0, \infty)\{\alpha_K = 0\}^\varepsilon$. As the sum of a compact set and a closed set, K_ε is evidently closed. So it remains to check convergence. Fix $z \notin K$; assume without loss of generality that $z_1 > 0$ since otherwise $z \notin K^\varepsilon$ as soon as $\{\alpha_K = \infty\}^\varepsilon \subset (H_{-e_1}^-)^c$. Let $A = \{x: x_1 = z_1\} \cap K$. For every $y \in K$ with $y_1 \leq z_1$ and every u such that $\alpha_K(u) = \infty$, the ray $y + [0, \infty)u$ intersects $\{x_1 = z_1\}$ inside A . Let us assume that $y + tu \in A$ is such a point of intersection. Then $t = (z_1 - y_1)/\langle u, e_1 \rangle$. Set

$$b(z) = z_1 + \min\{|y_1|: y \in K \text{ and } y_1 \leq 0\}, \quad c_\varepsilon = \inf\{\langle u, e_1 \rangle: u \in \{\alpha_K = \infty\}^\varepsilon\}.$$

Clearly $c_\varepsilon > c_0/2 > 0$ if $\varepsilon > 0$ is sufficiently small. Thus, if $v \in \{\alpha_K = \infty\}^\varepsilon$, $y \in K$ with $y_1 \leq z_1$, and $y + t'v \in \{x_1 = z_1\}$, then $y + t'v$ is included in the $(2b(z)/c_0^2 \cdot \varepsilon)$ -fattening of A . Hence, for small enough ε , z does not belong to $K_\varepsilon \cap \{x_1 = z_1\}$. $\square$

Recall that the width function w , given by (1.11), comprises the half-plane velocities of Euclidean threshold growth dynamics. Our next task is to derive some basic properties of w . When combined with formula (1.15) and Proposition A2, these results will enable us to deduce conclusions about the limiting shape L from regularity properties of the neighbor set $\mathcal{N}$.

Proposition A3. *The function w is always continuous. In case $\mathcal{N} \subset \mathbb{R}^d$ is a bounded connected open set with continuous boundary $\partial\mathcal{N}$, assume additionally that for each $u \in \mathcal{S}$ and all real λ ,*

$$(A.10) \quad \sigma(\{x \in \partial\mathcal{N}: \langle x, u \rangle = \lambda\}) = 0,$$

where σ denotes volume in $d - 1$ dimensions. Then w is $\mathcal{C}^1$ on the set $\{w > 0\}$.

Proof. Define $V: \mathcal{S} \times [0, \infty) \rightarrow [0, \infty)$ by $V(u, \lambda) = |(H_u^- - \lambda u) \cap \mathcal{N}|$. Then w is given implicitly by $V(u, w(u)) = \theta$. The proof of continuity is straightforward. To demonstrate differentiability, set $A = A(u, \lambda) = \{x \in \mathcal{N}: \langle x + \lambda u, u \rangle = 0\}$. Using (A.10) it is not hard to show that

$$\frac{\partial V}{\partial \lambda} = \sigma(A) \quad \text{and} \quad \frac{\partial V}{\partial u}(y) = \int_A \langle y, x \rangle \sigma(dx),$$

where y is any vector in the tangent plane at $u \in \mathcal{S}$. Both partial derivatives are clearly continuous since A changes continuously. Moreover, if $w(u) > 0$, then $\sigma(A(u, \lambda)) > 0$ as soon as $V(u, \lambda) = \theta$. An application of the Implicit Function Theorem finishes the proof. In fact,

$$\frac{\partial w}{\partial u}(y) = \frac{-\int_{A(u, w(u))} \langle y, x \rangle \sigma(dx)}{\sigma(A(u, w(u)))}.$$

(Similar reasoning shows that for each $k \geq 0$, w is $\mathcal{C}^{k+1}$ if the boundary of $\mathcal{N}$ is $\mathcal{C}^k$.) $\square$

In two dimensions, $K_{1/w}$ inherits convexity from $\mathcal{N}$ provided that $\mathcal{N}$ is smooth, strictly convex, and satisfies a symmetry assumption. As far as we can tell the proof below does not extend to $d \geq 3$ unless $\mathcal{N}$ is smooth and θ is less than some small $\theta_0(\mathcal{N})$. Indeed, we believe there are counterexamples to the three-dimensional analog of the following result.

Proposition A4. *Assume that $d = 2$ and $-\mathcal{N} = \mathcal{N}$.*

(a) *If $\mathcal{N}$ is convex, then $K_{1/w}$ is convex for every θ .*

(b) *If $\mathcal{N}$ is strictly convex, then $K_{1/w}$ is strictly convex for every θ .*

Proof. (a) K_α is convex iff for each $u, v \in \mathcal{S}$,

$$\frac{\alpha(u)\alpha(v)}{\alpha(u) + \alpha(v)} \|u + v\| \leq \alpha\left(\frac{u + v}{\|u + v\|}\right).$$

Thus we need to prove that

$$w(u) + w(v) \geq w\left(\frac{u + v}{\|u + v\|}\right) \cdot \|u + v\|,$$

or equivalently, with V defined as in the proof of Proposition A3, and setting $r = (u + v)/\|u + v\|$,

$$(A.11) \quad V(u, \lambda) = \theta \quad \text{and} \quad V(v, \mu) = \theta \Rightarrow V\left(r, \frac{\lambda + \mu}{\|u + v\|}\right) \leq \theta.$$

Given $\lambda \neq \mu$, choose x so that $\langle x, u \rangle = \lambda$ and $\langle x, v \rangle = \mu$. Let l_0 be the line containing $\mathbf{0}$ and x , and for $\varphi \in [0, \pi]$, let l_φ be the line that makes angle φ with respect to l_0 . (Choose the normal to l_0 in some canonical way to ensure uniqueness of l_φ .) Now define $F: [0, \pi] \rightarrow [0, \infty)$ by

$$F(\varphi) = |\text{the component of } (\mathcal{N} \cap l_\varphi)^c \text{ that does not include } \mathbf{0}|.$$

To show (A.11), it suffices to check that F cannot have a local maximum in $(0, \pi)$. Clearly we can assume that $x \in \mathcal{N}$. Also, without loss of generality, suppose that $\mathcal{N}$ is strictly convex with differentiable boundary. (A straightforward approximation then handles the general convex case.) With b, c, β and γ as indicated in Figure 6 below, we have

$$\frac{dF}{d\varphi} = \frac{1}{2}(b(\varphi)^2 - c(\varphi)^2), \quad \frac{d^2F}{d\varphi^2} = -(b(\varphi)^2 \cotan \beta(\varphi) + c(\varphi)^2 \cotan \gamma(\varphi)).$$

By strict convexity and symmetry of $\mathcal{N}$, $\cotan \beta + \cotan \gamma < 0$ for every φ . Thus $F''(\varphi) > 0$ whenever $F'(\varphi) = 0$ and the only critical point is a local minimum. Claim (a) follows. Now assume that $1/w$ is *not* strictly convex. By suitably rotating $\mathcal{N}$ we can assume that $w(\varphi) = w(0) \cos \varphi$ in some neighborhood of $\varphi = 0$, where φ is the polar coordinate. But then the function F above has derivative 0 over an open subinterval of $(0, \pi)$. As we have already seen, this is impossible. $\square$

In conclusion, let us mention some implications of Propositions A2–A4 for the limiting shape L of threshold growth dynamics when formula (1.15) applies. Propositions A2(b) and A3 ensure that L is d -dimensional provided (1.16) holds, precisely the hypothesis we need in our proof of Theorem 1. Under this assumption, Proposition A2(a)–(b) implies that L is always a convex set containing $\mathbf{0}$, and either L contains a neighborhood of $\mathbf{0}$ or the closure of

FIGURE 6

the support of α_L is a “generalized cone” formed by an intersection of half-spaces H_u^- . Propositions A2(c) and A3 then provide a general criterion for the validity of computational formula (A.4). Similarly Proposition A2(d) can be applied to identify directions in which α_L is not differentiable.

Two particularly nice results follow from Propositions A2(f), A3, and A4(b). Assume that $\mathcal{N}$ is bounded, connected and open, with continuous boundary, that (A.10) holds, and $w(u) > 0$ for all u . Then in any $d \geq 2$, L is strictly convex. If $d = 2$, and $\mathcal{N}$ is closed, strictly convex and symmetric ($-\mathcal{N} = \mathcal{N}$), then the boundary of L is $\mathcal{C}^1$. Two-dimensional examples such as those in §2 show that the boundary of L can have flat regions if $w(u) = 0$ in certain directions, and the boundary of L can have “corners” if the boundary of $\mathcal{N}$ has flat regions.
